Williams GYNECOLOGY

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

IN MEMORIAM

Kristin Paulson Landon

Early in production of this edition, our *Williams* family lost a dedicated member of the team in Ms. Kristin Landon. We knew her as our valued copyeditor for many editions of both *William Obstetrics* and *Williams Gynecology*. However, Kristin's life was multifaceted, with talents that included analytic chemist, musician, cooking enthusiast, and writer. Indeed, her published science fiction novels include the *Hidden Worlds* trilogy and *Windhome*. We knew Kristin as an integral member of our textbook team. Her precision added clarity to our efforts and made our textbooks better.

DEDICATION

This edition of Williams Gynecology is dedicated to Dr. Karen Bradshaw, who has served as an Editor of Williams Gynecology since its inaugural edition. We are especially grateful for her tenacity during the formative years of our project and her academic support to bring our first edition to print. Our text's content has benefited greatly from her clinical acumen coupled with a mastery of the evidence-based literature. Her clear, concise chapters distilled challenging reproductive endocrinology tenets into easily understood concepts that translate to the bedside. Indeed, her many teaching awards throughout her career attest to this gift.

Dr. Bradshaw's roots at the University of Texas Southwestern run deep and include her medical school years, residency training, and fellowship study in Reproductive Endocrinology and Infertility. Early in her career as a faculty member at UTSW, she became Director of the Assisted Reproductive Technologies Program. Subsequently, she helped develop the Pediatric Gynecology Service at Children's Hospital, which was a first for Dallas and continues to this day. This was the first of many collaborative and multidisciplinary projects that typify her career. As another example, she was instrumental in expanding the field of minimally invasive surgery (MIS) at our institution and initiated the Laparoscopy Teaching Service. She partnered with the Department of Surgery and was provided a joint appointment to foster MIS development. She served on the Southwestern Minimally Invasive Surgery Executive Committee from its inception in 1997 until her retirement in 2019.

In addition to academics, Dr. Bradshaw was clinically and administratively active in our expanding private practice on campus. As an advocate of health for women as they entered and advanced through menopause, she was the first holder of the Helen J. and Robert S. Strauss and Diana L. and Richard C. Strauss Distinguished Professorship in Women's Health. Her vision led to development of a single, multidisciplinary site to care for the various health aspects of mature women. This was subsequently endowed and became the Lowe Foundation Center for Women's Preventative Health Care.

During her academic career, Dr. Bradshaw promoted academic excellence at UTSW. She served administratively on numerous academic committees involved with medical school, residency, and specialty training. Moreover, Karen was a passionate advocate for the advancement of women in academia at our institution. She was also a voice on the national academic stage. Karen served on the Board of the American Society of Reproductive Endocrinology and Infertility and extensively participated in their postgraduate training efforts. She filled prominent leadership roles in the Society for Reproductive Endocrinology and Infertility, including president. In both organizations, she actively advanced both residency and fellowship training in the specialty.

For us in the Department of Obstetrics and Gynecology, Dr. Bradshaw has played an important role as mentor and colleague. Her experience and clinical expertise have been invaluable, and she has provided guidance for challenging gynecology cases. On so many levels, we have benefitted greatly from her academic and clinical contributions.

CONTENTS

Editors xv
Contributors xvii
Artists xxi
Preface xxiii
Acknowledgments xxv

SECTION 1

GENERAL GYNECOLOGY

1. Well Woman Care 2
2. Techniques Used for Imaging in Gynecology 29
3. Gynecologic Infection 56
4. Benign Disorders of the Lower Reproductive Tract 92
5. Contraception and Sterilization 111
6. First-Trimester Abortion 137
7. Ectopic Pregnancy 161
8. Abnormal Uterine Bleeding 179
9. Benign Uterine Pathology 204
10. Benign Adnexal Mass 219
11. Endometriosis 233
12. Pelvic Pain 253
13. Breast Disease 279
14. Psychosocial Issues and Female Sexuality 302
15. Pediatric and Adolescent Gynecology . . . 320

SECTION 2

REPRODUCTIVE ENDOCRINOLOGY, INFERTILITY, AND THE MENOPAUSE

16. Reproductive Endocrinology 336
17. Amenorrhea 371
18. Polycystic Ovarian Syndrome and Hyperandrogenism 389
19. Anatomic Disorders 406
20. Evaluation of the Infertile Couple 428
21. Treatment of the Infertile Couple 450
22. Menopause and the Mature Woman 473

SECTION 3

FEMALE PELVIC MEDICINE AND RECONSTRUCTIVE SURGERY

23. Urinary Incontinence 512
24. Pelvic Organ Prolapse 536
25. Anal Incontinence, Anorectal Disorders, and Rectovaginal Fistula 558
26. Genitourinary Fistula and Urethral Diverticulum 574

SECTION 4

GYNECOLOGIC ONCOLOGY

27. Principles of Chemotherapy 588
28. Principles of Radiation Therapy 606
29. Preinvasive Lesions of the Lower Anogenital Tract 620
30. Cervical Cancer 654
31. Vulvar Cancer 676
32. Vaginal Cancer 691
33. Endometrial Cancer 699
34. Uterine Sarcoma 722
35. Epithelial Ovarian Cancer 732
36. Ovarian Germ Cell and Sex Cord–Stromal Tumors 756
37. Gestational Trophoblastic Disease 774

SECTION 5

ASPECTS OF GYNECOLOGIC SURGERY

38. Anatomy 792
39. Preoperative Considerations 822
40. Intraoperative Considerations.....839
41. Minimally Invasive Surgery Fundamentals 873
42. Postoperative Considerations 907

SECTION 6

ATLAS OF GYNECOLOGIC SURGERY

43. Surgeries for Benign Gynecologic Disorders..... 930
43-1. Midline Vertical Incision 930
43-2. Pfannenstiel Incision 933
43-3. Cherney Incision 936
43-4. Maylard Incision 938
43-5. Ovarian Cystectomy.....939
43-6. Salpingo-oophorectomy 941
43-7. Interval Partial Salpingectomy.....943
43-8. Salpingectomy and Salpingostomy... 945
43-9. Cornuostomy and Cornual Wedge Resection 947
43-10. Abdominal Myomectomy 951
43-11. Vaginal Myomectomy.....954
43-12. Abdominal Hysterectomy 956
43-13. Vaginal Hysterectomy.....965
43-14. Trachelectomy.....970
43-15. Suction Dilation and Curettage.....972
43-16. Sharp Dilation and Curettage.....976
43-17. Hymenectomy.....978
43-18. Bartholin Gland Duct Incision and Drainage.....980
43-19. Bartholin Gland Duct Marsupialization 982
43-20. Bartholin Gland Duct Excision 984
43-21. Vulvar Abscess Incision and Drainage 986
43-22. Vestibulectomy 988
43-23. Labia Minora Reduction 990
43-24. Defibulation 992
43-25. Vaginal Septum Excision 993
43-26. Neovagina Creation.....995
43-27. Excision of Preinvasive Cervical Lesions.....999
43-28. Ablation of Preinvasive Cervical Lesions..... 1004
43-29. Treatment of Vulvar Intraepithelial Neoplasia 1006
44. Minimally Invasive Surgery 1016
44-1. Diagnostic Laparoscopy..... 1016
44-2. Laparoscopic Sterilization and Essure Removal 1019
44-3. Laparoscopic Salpingectomy..... 1025
44-4. Laparoscopic Salpingostomy..... 1028
44-5. Laparoscopic Ovarian Cystectomy..... 1030
44-6. Laparoscopic Salpingo-oophorectomy..... 1034
44-7. Ovarian Drilling 1036

44-8. Laparoscopic Myomectomy and Leiomyoma Ablation 1037
44-9. Laparoscopic Hysterectomy 1043
44-10. Laparoscopic Supracervical Hysterectomy 1047
44-11. Total Laparoscopic Hysterectomy 1050
44-12. Diagnostic Hysteroscopy 1054
44-13. Hysteroscopic Polypectomy 1056
44-14. Hysteroscopic Myomectomy 1058
44-15. Endometrial Ablation Procedures 1061
44-16. Hysteroscopic Septoplasty 1065
44-17. Proximal Fallopian Tube Cannulation 1067
44-18. Lysis of Intrauterine Adhesions 1069

45. Surgeries for Pelvic Floor Disorders 1075

45-1. Diagnostic and Operative Cystoscopy and Cystourethroscopy 1075
45-2. Lower Urinary Tract Injury Repair ... 1080
45-3. Burch Colposuspension 1091
45-4. Retropubic Midurethral Sling 1094
45-5. Transobturator Midurethral Sling ... 1097
45-6. Pubovaginal Sling 1099
45-7. Urethral Bulking Injections 1101
45-8. Urethrolysis 1103
45-9. Midurethral Sling Release 1105
45-10. Urethral Diverticulum Repair 1106
45-11. Martius Bulbospongiosus Fat Pad Flap 1109
45-12. Sacral Neuromodulation 1111
45-13. Anterior Colporrhaphy 1114
45-14. Abdominal Paravaginal Defect Repair 1117
45-15. Posterior Colporrhaphy 1119
45-16. Perineorrhaphy 1122
45-17. Abdominal Sacrocolpopexy 1124
45-18. Minimally Invasive Sacrocolpopexy 1129
45-19. Vaginal Uterosacral Ligament Suspension 1133
45-20. Abdominal Uterosacral Ligament Suspension 1136
45-21. Sacrospinous Ligament Fixation 1138
45-22. McCall Culdoplasty 1143
45-23. Colpocleisis 1145
45-24. Anal Sphincteroplasty 1150
45-25. Rectovaginal Fistula Repair 1153

46. Surgeries for Gynecologic Malignancies 1160

46-1. Radical Abdominal Hysterectomy (Type III) 1160
46-2. Modified Radical Abdominal Hysterectomy (Type II) 1166
46-3. Minimally Invasive Radical Hysterectomy 1168
46-4. Total Pelvic Exenteration 1174
46-5. Anterior Pelvic Exenteration 1180
46-6. Posterior Pelvic Exenteration 1181
46-7. Incontinent Urinary Conduit 1182
46-8. Continent Urinary Conduit 1186
46-9. Vaginal Reconstruction 1190
46-10. Pelvic Lymphadenectomy 1194
46-11. Paraaortic Lymphadenectomy 1197
46-12. Minimally Invasive Staging for Gynecologic Malignancies 1201
46-13. En Bloc Pelvic Resection 1207
46-14. Omentectomy 1211
46-15. Splenectomy 1213
46-16. Diaphragmatic Surgery 1215
46-17. Colostomy 1217
46-18. Large Bowel Resection 1220
46-19. Ileostomy 1222

46-20. Small Bowel Resection 1223
46-21. Low Anterior Resection 1225
46-22. Intestinal Bypass 1229
46-23. Appendectomy 1231
46-24. Skinning Vulvectomy. 1233
46-25. Radical Partial Vulvectomy 1235
46-26. Radical Complete Vulvectomy. 1238
46-27. Inguinofemoral Lymphadenectomy 1241
46-28. Reconstructive Grafts and Flaps 1244

PREFACE

Williams Gynecology provides a thorough, evidence-based presentation of gynecology's depth and breadth. In Section 1, general gynecology topics are covered. Section 2 provides chapters covering reproductive endocrinology and infertility. The developing field of female pelvic medicine and reconstructive surgery is presented in Section 3. In Section 4, gynecologic oncology is discussed.

Traditionally, gynecologic information has been offered either as a didactic text or a surgical atlas. Instead, because the day-to-day activity of a gynecologist blends these two, we did the same with our text. The initial four sections of our book describe the evaluation and medical treatment of gynecologic problems. The remaining two sections focus on the surgical patient. Section 5 offers detailed anatomy and a discussion of perioperative considerations. Our final section presents an illustrated atlas for the surgical correction of conditions described in Sections 1 through 4. In addition, chapters are extensively complemented by illustrations, photographs, diagnostic algorithms, and treatment tables. To interconnect this content, readers will find page references within one chapter that will direct them to complementary content in another.

ACKNOWLEDGMENTS

During the creation and production of our textbook, we were lucky to have the assistance and support of countless talented professionals both within and outside our department. First, a task of this size could not be completed without the unwavering support provided by our Department Chairman, Dr. Steven Bloom, and Vice-Chairpersons, Drs. Barry Schwarz and Catherine Spong. Their financial and academic endorsement of our efforts has been essential. Without their academic vision, this undertaking could not have flourished. In addition, Dr. F. Gary Cunningham provided the academic vision that led to the creation of this text. Dr. Cunningham has been the senior author for eight editions of Williams Obstetrics. His dedication to evidence-based medicine set the bar on which our textbook was built. We feel privileged to have learned the craft of clear, concise academic summary from a consummate master.

In constructing a compilation of this breadth, physicians from several departments and their expertise were needed to add vital, contemporaneous information. From the Department of Pathology, Dr. Kelley Carrick shared her expertise and generously shared from her cadre of outstanding images. She translated her extensive knowledge of gynecologic pathology into concepts relevant for the general gynecologist. We appreciate the contributions of Dr. Agnieszka Dombrowska of Johns Hopkins University. She added her great expertise to our chapter on breast disease. Dr. Kevin Doody lent his considerable clinical and academic prowess in the treatment of infertility. He was also a kind benefactor of many spectacular clinical photographs and contributed these generously to numerous chapters. This is also true of Dr. David Rogers, Ellen Wilson, and William Griffith, who have been champions in expanding our academic image library. Sonographer Jason McWhirt at Parkland Hospital has similarly been a tremendous advocate in securing images of common and unique gynecologic pathology. In sum, their stunning images add to the academic richness of this edition.

New beautiful and detailed artwork in our atlas this edition was drawn by Mr. Lewis Calver. Again for this edition, he paired his academic talents with Dr. Marlene Corton to create urogynecologic images. Lew also partnered with Drs. Cherine Hamid, Patrick Weix, and Kimberly Kho to create academically new presentations for other sections of our surgical atlas. These renderings were crafted and tailored with the gynecologic surgeon in mind to depict important techniques and anatomy for these surgeries. We also acknowledge our atlas artists from the first three editions, who are listed in subsequent pages.

We are truly indebted to our administrative staff. For this project, we were lucky to have Ms. Toshia Lee serve as our primary administrative assistant. We greatly appreciated her cheery professionalism, relentless commitment to our project, and efficiency. Our words fall well short in expressing our gratitude to her for her heroic efforts. She was assisted by Ms. Regina Williams and Ms. Tabitha Brumfield. Their dedicated work ethic, eagerness to assist, attention to detail, and pleasant professionalism made our chapters crisp and accurate. None of our image and text production would have been possible without brilliant information technology support. Knowledgeable and responsive, Mr. Charles Richards has assisted our project since the first edition. We could not do our job without his expertise.

Williams Gynecology was sculpted into its final form by the talented and dedicated group at McGraw-Hill Education. Senior Project Development Editor Ms. Christie Naglieri has brought her considerable publishing knowledge, energetic work ethic, and creativity to our project. Her attention to detail and organizational talents have kept our project on track with efficiency and style. Ms. Leah Carton served as editorial coordinator, and we extend warm thanks for her tremendous support. Her efficiency, professionalism, hard work, accuracy, and positive attitude made coordination of this project a dream. Mr. Rick Ruzycka served as production supervisor and has been a long-time advocate of our books. We are so appreciative of his expertise and knowledge. Executive Editor Mr. Jason Malley has taken our project under his care and has adeptly shepherded it to completion. We happily look forward to many future collaborative editions together.

Without the thoughtful, creative efforts of many, our textbook would be a barren wasteland of words. Integral to this process is Jason M. McAlexander, Biomedical Media Manager at MPS North America, LLC. His artistic team assisted us in creating and revising many of our text images. Their attention to detail and accurate renderings added important academic support to our words.

Our text took its final shape under the watchful care of our compositors at Aptara, Inc. Specifically, we thank Ms. Indu Jawwad for her talents in skillfully and expediently coordinating and overseeing composition. Her dedicated attention to detail and organization were vital to completion of our project. Her pleasant professionalism was appreciated daily. Also at Aptara, Mr. Mahender Singh served a crucial task of quality control and assisted in creating beautiful chapter layouts to highlight our content aesthetically and informatively. We thank the entire Aptara team for their dedication to our books. Special thanks go to Mr. Greg Feldman. As copyeditor for our project, Greg has added precision and clarity to our efforts. His pleasant professionalism and expertise has made our text better.

We offer a sincere "thank you" to our residents in training. Their curiosity keeps us energized to find new and effective ways to convey age-old as well as cutting-edge concepts. Their logical questions lead us to holes in our text, and thereby, always help us to improve our work. Moreover, many of the photographs in this textbook were gathered with the help of our many residents.

Furthermore, the contributors to this text owe a significant debt to the women who have allowed us to participate in their care. The images and clinical expertise presented in this text would not have been possible without their collaborative spirit to help us move medical knowledge forward.

Lastly, we offer an enthusiastic and heartfelt "thank you" to our families and friends. Without their patience, generosity, and encouragement, this task would have been impossible. For them, too many hours with "the book" left them with new responsibilities. And importantly, time away from home left precious family memories and laughs unrealized. We sincerely thank you for your love and support.

Serving as both specialist and primary care provider, gynecologists provide patient screening, emphasize ideal health behaviors, and coordinate appropriate consultation for care beyond their scope of practice. Various organizations provide regularly updated preventive care recommendations. Guidelines commonly accessed are those from the American College of Obstetricians and Gynecologists (ACOG), Centers for Disease Control and Prevention (CDC), U.S. Preventive Services Task Force (USPSTF), and American Cancer Society.

MEDICAL HISTORY

During a comprehensive well woman visit, patients are first queried regarding new or ongoing illness. To assist with evaluation, complete medical, social, surgical, and family histories are obtained. Specific gynecologic topics usually cover current and prior contraceptives; results from prior sexually transmitted disease (STD) testing, cervical cancer screening, or other gynecologic tests; sexual history, described in Chapter 3; and menstrual history, outlined in Chapter 8. Obstetric questions chronicle circumstances around deliveries, losses, or complications. Screening for intimate partner violence or depression is also completed (Chap. 14). Discussion might also assess the patient's support system and any cultural or spiritual beliefs that might affect her general health care. Last, a review of systems, whether performed by the clinician or office staff, can add clarity to new patient problems.

PHYSICAL EXAMINATION

Breast Examination

Many women present to their gynecologist with complaints specific to the breast or pelvis. Accordingly, these are often areas of increased focus, and their evaluation is described here.

Self breast examination (SBE) is an examination performed by the patient herself to detect abnormalities. In contrast, clinical breast examination (CBE) is completed by a health care professional and may identify a small portion of breast malignancies not detected with mammography. In addition, CBE may identify cancer in young women, who are not typical candidates for mammography (McDonald, 2004). Overall, however, studies show that SBE and CBE raise diagnostic testing rates for ultimately benign breast disease and are ineffective in lowering breast cancer mortality rates (Kösters, 2008; Thomas, 2002). Accordingly, several organizations have removed SBE and CBE from their recommended screening practices (Oeffinger, 2015; Siu, 2016). However, the American College of Obstetricians and Gynecologists (2017b) encourages breast self-awareness, which focuses on breast appearance and architecture and may include SBE. It also recommends that women receive a CBE every 1 to 3 years between ages 20 and 39. At age 40, CBE is completed annually. Specific mammography guidelines are listed in Chapter 13.

During CBE, the breasts are initially viewed as a woman sits on the table's edge with hands placed at her hips and with pectoralis muscles flexed. Alone, this position enhances asymmetry. Additional arm positions, such as placing arms above the head, do not add vital information. Breast skin is inspected for breast erythema; retraction; scaling, especially over the nipple; and edema, which is termed peau d'orange change. The breast and axilla are also observed for contour symmetry.

Following inspection, axillary, supraclavicular, and infraclavicular lymph nodes are palpated most easily with a woman seated and her arm supported by the examiner (Fig. 1-1). The axilla is bounded by the pectoralis major muscle ventrally and the latissimus dorsi muscle dorsally. Lymph nodes are detected as the examiner's hand glides from high to low in the axilla and momentarily compresses nodes against the lateral chest wall. In a thin patient, one or more normal, mobile lymph nodes less

mebookstree

FIGURE 1-1 One method of axillary lymph node palpation. Finger tips extend to the axillary apex and compress tissue against the chest wall in the rolling fashion shown in Figure 1-2. The patient's arm is supported by the examiner.

than 1 cm in diameter may commonly be appreciated. The first lymph node to become involved with breast cancer metastasis (the sentinel node) is nearly always located just behind the midportion of the pectoralis major muscle belly.

Breast palpation is completed with a woman supine and with one hand above her head to stretch breast tissue across the chest wall. Examination includes breast tissue bounded by the clavicle, sternal border, inframammary crease, and midaxillary line. Breast palpation within this pentagonal area is approached in a linear fashion. Technique uses the finger pads in a continuous rolling, gliding, circular motion (Fig. 1-2). At each palpation point, tissue is assessed both superficially and deeply.

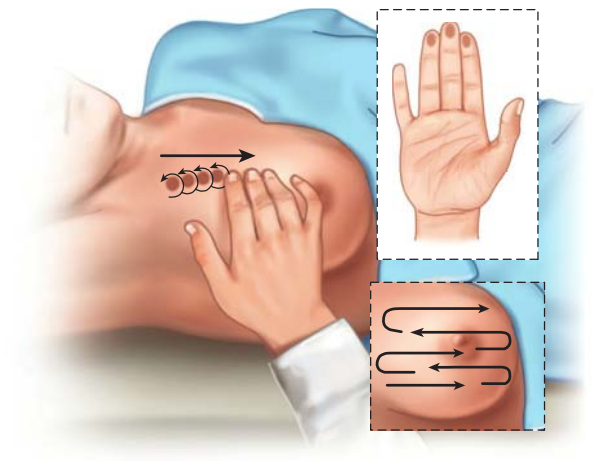

FIGURE 1-2 Recommended patient positioning and palpation technique. One inset shows the path of palpation. The other illustrates use of finger pads and a circular rolling motion to palpate the entire breast.

During CBE, intentional attempts at nipple discharge expression are not required unless a *spontaneous* discharge has been described by the patient.

If abnormal breast findings are noted, they are described by their location in the right or left breast, clock position, distance from the areola, and size. Evaluation and treatment of breast and nipple diseases are described in Chapter 13.

During examination, patients are educated that new axillary or breast masses, noncyclic breast pain, spontaneous nipple discharge, new nipple inversion, and breast skin changes such as dimpling, scaling, ulceration, edema, or erythema should prompt evaluation. This constitutes breast self-awareness. Patients who desire to perform SBE are counseled on its benefits, limitations, and potential harms and instructed to complete SBE the week after menses.

Pelvic Examination

Pelvic examination is typically performed with a patient supine, legs in dorsal lithotomy position, and feet resting in stirrups. The head of the bed is elevated 30 degrees to relax abdominal wall muscles for bimanual examination. A woman is assured that she may stop or pause the examination at any time. Moreover, each part of the evaluation is announced or described before its performance. Recommended STD screening is discussed prior to examination, and necessary samplers are assembled (Table 1-1).

Inguinal Lymph Nodes and Perineal Inspection

Pelvic cancers and infections may drain to the inguinal lymph nodes, and these are palpated during examination. Following this, a methodical inspection of the perineum extends from the mons pubis ventrally, to the labiocrural folds laterally, and to the anus. Notably, infections and neoplasms that involve the vulva can also involve perianal skin. Some clinicians additionally palpate for Bartholin and paraurethral gland pathology. However, in most cases, patient symptoms and asymmetry in these areas will dictate the need for this specific evaluation.

Speculum Examination

Both metal and plastic specula are available for this examination, each in various sizes to accommodate vaginal length and laxity. The plastic speculum may be equipped with a small light that provides illumination, whereas metal specula require an external light source. Preference between these two types is provider dependent.

The vagina and cervix are typically viewed after placement of either a Graves or Pederson speculum (Fig. 1-3). Prior to insertion, a speculum may be warmed with running water or by warming lights built into some examination tables. In addition, lubrication may add comfort to insertion. Gel lubricants do not raise unsatisfactory Pap smear cytology rates or decrease *Chlamydia trachomatis* detection rates compared with water (Griffith, 2005). If gel lubrication is used, a dime-sized aliquot is applied sparingly to the outer surface of the speculum blades.

Immediately before insertion, the labia minora are gently separated, and the urethra is identified. Because of urethral sensitivity, the speculum is inserted well below the meatus. Alternatively, prior to speculum placement, an index finger may be placed in the vagina, and pressure exerted against the

TABLE 1-1. Sexually Transmitted Disease Screening Guidelines for Nonpregnant, Sexually Active Asymptomatic Women

Infectious Agent	Screening Recommendations	Risk Factors
C trachomatis + *N gonorrhoeae*	All ≤24 yr; those older with risks Timing: annually or if new or persistent factors since last negative result	New or multiple partners; partner with STD or multiple partners; inconsistent condom use; sex work; current or prior STD
T pallidum	Those with risks	Sex work; incarceration; HIV; high local prevalence
HIV virus	All 13–64 yr: one time[a] Those with risks: periodically	Multiple partners; injection drug use; sex work; concurrent STD; MSM; at-risk partners; initial TB diagnosis
HCV	All born from 1945 to 1965: one time Those with risk factors: periodically	Injection/intranasal drug use; dialysis; infected mother; blood products before 1992; unregulated tattoo; high-risk sexual behavior
HBV	Those with risk factors	HIV; injection drug use; affected family or partner; multiple partners; high-prevalence country of origin[b]
HSV	No routine screening	

[a]Centers for Disease Control and Prevention (2015) and American College of Obstetricians and Gynecologists (2017d) recommend one-time screening between ages 13 and 64 years. The U.S. Preventive Services Task Force uses a 15–65 yr age range.
[b]Regions of the world with high or intermediate prevalence of include much of Eastern Europe, Asia, Africa, the Middle East, and the Pacific Islands.
C trachomatis = *Chlamydia trachomatis*; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; HSV = herpes simplex virus; MSM = men having sex with men; *N gonorrhoeae* = *Neisseria gonorrhoeae*; STD = sexually transmitted disease; TB = tuberculosis; *T pallidum* = *Treponema pallidum*.

posterior wall. A woman is then encouraged to relax this wall to improve comfort with speculum insertion. This practice may prove especially helpful for women undergoing their first examination and for those with infrequent coitus, dyspareunia, or heightened anxiety.

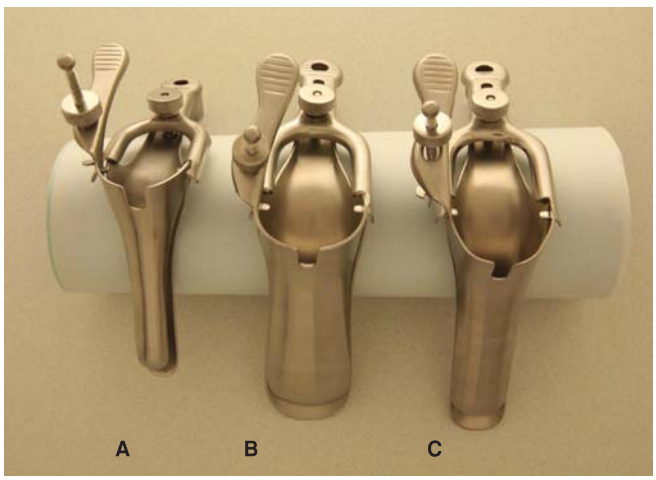

FIGURE 1-3 Vaginal specula. **A.** Pediatric Pederson speculum. This may be selected for child, adolescent, or virginal adult examination. **B.** Graves speculum. This may be selected for examination of parous women with relaxed or collapsing vaginal walls. **C.** Pederson speculum. This may be selected for sexually active women with adequate vaginal wall tone. (Reproduced with permission from US Surgitech, Inc.)

With speculum insertion, the vagina commonly contracts, and a woman may note pressure or discomfort. A pause at this point typically is followed by vaginal muscle relaxation. As the speculum bill is completely inserted, it is angled approximately 30 degrees downward to reach the cervix. Commonly, the uterus is anteverted, and the ectocervix lies against the posterior vaginal wall.

As the speculum is opened, the ectocervix can be identified. Vaginal walls and cervix are inspected for masses, ulceration, or unusual discharge. As outlined in Chapter 29, cervical cancer screening is often completed. Additional swabs for STD screening, culture, or microscopic evaluation can be collected as needed.

Bimanual Examination

Most often, the bimanual examination is performed after the speculum evaluation. Some clinicians prefer to complete the bimanual portion first to better identify cervical location prior to speculum insertion. Either process is appropriate. Uterine and adnexal size, mobility, and tenderness can be assessed during this examination. For women with prior hysterectomy and adnexectomy, bimanual examination is still valuable and can be used to exclude other pelvic pathology.

To begin, a gloved index and middle finger are inserted together into the vagina until the cervix is reached. To ease insertion, a water-based lubricant can be initially applied to these gloved fingers. Once the cervix is reached, uterine orientation can be quickly assessed by sweeping the index finger inward along the

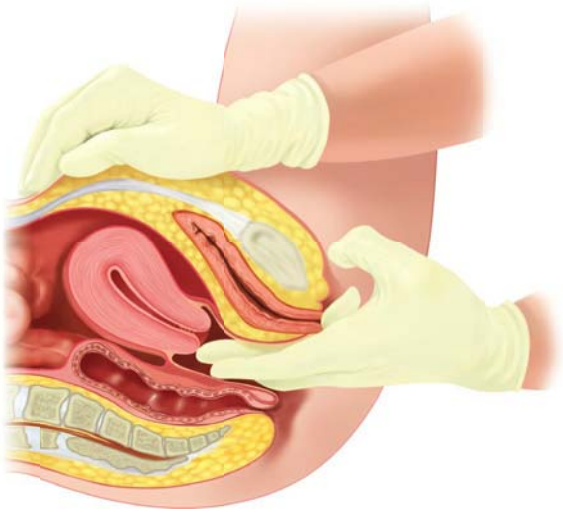

FIGURE 1-4 Bimanual examination. Fingers beneath the cervix lift the uterus toward the anterior abdominal wall. A hand placed on the abdomen detects upward pressure from the uterine fundus. Examination allows assessment of uterine size, mobility, and tenderness.

anterior surface of the cervix. In those with an anteverted position, the uterine isthmus is noted to sweep upward, whereas in those with a retroverted position, a soft bladder is palpated. However, in those with a retroverted uterus, if a finger is swept along the cervix's posterior aspect, the isthmus is felt to sweep downward. With a retroverted uterus, this same finger is continued posteriorly to the fundus and then side-to-side to assess uterine size and tenderness.

To determine the size of an anteverted uterus, fingers are placed beneath the cervix, and upward pressure tilts the fundus toward the anterior abdominal wall. A clinician's opposite hand is placed against the abdominal wall to locate the upward fundal pressure (Fig. 1-4).

To assess adnexa, the clinician uses two vaginal fingers to lift the adnexa from the posterior cul-de-sac or from the ovarian fossa toward the anterior abdominal wall. The adnexum is trapped between these vaginal fingers and the clinician's other hand, which is exerting downward pressure against the lower abdomen. For those with a normal-sized uterus, this abdominal hand is typically best placed just above the inguinal ligament.

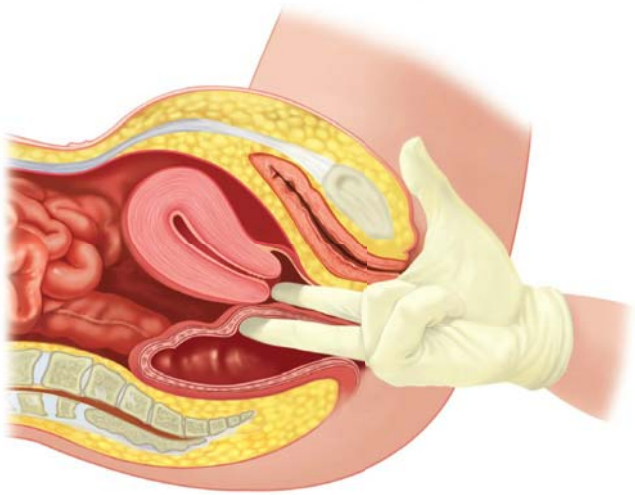

FIGURE 1-5 Rectovaginal examination.

Rectovaginal Examination

The decision to perform rectovaginal evaluation varies among providers. Some prefer to complete this evaluation on all adults, whereas others elect to perform rectovaginal examination for those with specific indications. These may include pelvic pain, an identified pelvic mass, rectal symptoms, or risks for colon cancer.

Gloves are changed between bimanual and rectovaginal examinations to avoid contamination of the rectum with potential vaginal pathogens. Initially, an index finger is placed into the vagina and a middle finger into the rectum (Fig. 1-5). These fingers are swept against one another in a scissoring fashion to assess the rectovaginal septum for scarring or peritoneal studding. The index finger is removed, and the middle finger completes a circular sweep of the rectal vault to exclude masses. If immediate diagnostic fecal occult blood testing is indicated, it may be performed with a sample from this portion of the examination. As noted later, this single fecal occult blood testing does not constitute adequate colorectal cancer screening.

Examination Interval

An initial reproductive health visit is recommended between ages 13 and 15 years (American College of Obstetricians and Gynecologists, 2016b). This visit initiates discussion between an adolescent and health care provider on issues of puberty, menstruation, contraception, and STD protection. Although not mandated, a pelvic examination may be necessary if gynecologic symptoms are described.

For women older than 21, the American College of Obstetricians and Gynecologists (2016c) recommends annual well woman visits for examination, screening, counseling, and immunizations based on age and risk factors. In many cases, physical examination includes a pelvic examination to assess specific symptoms or to complete cervical cancer or STD screening. However, outside these indications, the American College of Physicians, the American Academy of Family Physicians (2017), and USPSTF (2017) recommend against screening pelvic examination for asymptomatic, nonpregnant, adult women. They cite potential harms that include discomfort, anxiety, and overtreatment (Qaseem, 2014). In contrast, potential benefits are early detection of dermatologic changes or of vulvar or vaginal cancer. Thus, the American College of Obstetricians and Gynecologists (2018b) recommends a patient-provider discussion of the benefits and risks of pelvic examination in the asymptomatic, nonpregnant, adult woman who does not require genital screening.

Care of the Transgender Patient

"Transgender" refers to individuals whose gender identity, expression, and behavior differ from those typically associated with their gender assigned at birth (World Professional

TABLE 1-2. Gender Terminology

Transgender: Individuals whose gender identity, expression and behavior differ to varying degrees from those typically ascribed to their sex at birth
Cisgender: Individuals whose gender identity aligns with their sex at birth
Gender dysphoria: Distress that is caused by a discrepancy between a person's assigned gender at birth and the person's gender identity
Gender identity: An individual's intrinsic sense of being male, female, or an alternative gender (gender variant) that is independent of the gender assigned at birth
Sexual orientation: An individual's attraction to members of the same sex and/or a different sex (i.e., lesbian, gay, bisexual, heterosexual, or asexual)
Gender expression: The manner used by individuals to present themselves socially that may or may not be congruent with their gender identity
Gender variance/gender nonconformity: Expression of gender identity that that does not fully adhere to either male or female gender norms
Female-to-male (trans men): Individuals assigned female gender at birth who are changing to a more masculine body/gender role
Male-to-female (trans women): Individuals assigned male gender at birth who are changing to a more feminine body/gender role

Data from World Professional Association for Transgender Health, 2012.

Association for Transgender Health, 2012). Also, an individual's gender identity is independent of their sexual orientation or gender expression (Table 1-2). Despite agreement on these concepts, no definition of "transgender" is universally accepted.

In 2016 in the United States, an estimated 0.6 percent of adults, which approximates 1.4 million, identified as transgender (Flores, 2016). However, global prevalence rates of transgender populations have not been established. In part, differing behavioral expression of gender likely affects rates across cultures.

Despite growing awareness of transgender issues within the medical community, individuals continue to face significant barriers to both medical and mental health care (American College of Obstetricians and Gynecologists, 2011). For example, transgender adolescents compose up to 40 percent of homeless youth, and this can limit health care access (Ray, 2006). Further, medical schools teach little about sexuality in general and even less about the unique aspects of transgender health. This knowledge gap prepares few providers to address specific transgender needs (Mayer, 2008).

In 2017, the Endocrine Society updated clinical practice guidelines to provide an evidence-based standard for the care of transgender persons (Hembree, 2017). The American College of Obstetricians and Gynecologists (2011) urges obstetrician-gynecologists to be willing and able either to provide care for these individuals or to refer them for routine care or gender-affirming treatment. Thus, an understanding of current practices and long-term health risks is essential.

One first step in eliminating barriers is creation of a welcoming and inclusive clinical environment for transgender persons. Intake forms ideally incorporate sexual minorities in the gender field and use terms such as "relationship status" instead of "marital status." Providers begin the visit with an open dialogue that asks for a preferred name and pronoun.

A history of their gender experience ideally uses open-ended questions to ascertain the age at their initial transition, prior supplement or hormone use, and its duration. Importantly, not all transgender patients have undergone surgical transition, and many opt for medical therapy alone. Clarifying prior gender-affirming and sexual practices allows adequate assessment of an individual's medical risks and reproductive needs. Assumptions regarding a patient's sexual orientation or practices are best avoided (Gay and Lesbian Medical Association, 2006).

Prior to physical examination, each patient's individual comfort level with being examined is assessed. A problem-oriented examination usually suffices, and a genital examination is not indicated unless needed for a specific complaint or routine screening.

Medical Management of Gender Dysphoria

Gender dysphoria is the condition commonly ascribed to transgender individuals seeking medical care (see Table 1-2). The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) defines it as the distress experienced by persons whose gender identity is incongruent to the gender they were assigned at birth (American Psychiatric Association, 2013). This diagnosis is best made by a qualified mental health provider. Following diagnosis, initiation of proper gender-affirming hormone therapy improves health outcomes and quality of life in these individuals (Gorin-Lazard, 2012). Those with gender dysphoria often have concurrent psychosocial or psychiatric issues. Thus, patients receiving hormone therapy are recommended to receive continuing psychotherapy (Spack, 2013).

In female-to-male transgender persons, the primary goals of testosterone therapy are cessation of menses and virilization. An increase in muscle mass and decline in fat mass are other effects. Testosterone is typically administered intramuscularly (IM) or subcutaneously every 1 to 2 weeks. To induce puberty in adolescents, initial testosterone doses may begin at 25 mg weekly. Doses increase incrementally every 3 to 6 months to reach the typical adult maintenance dose, which is 50 to 100 mg weekly (Hembree, 2017). Creams and patches are not

TABLE 1-3. Medical Management of Gender Dysphoria

	Puberty Suppression	FTM	MTF
Medications	Provide GnRH analogues: Implant (histrelin) Intramuscular (leuprolide)	Testosterone Parenteral (IM or SC) Oral Transdermal	Estrogen Oral Transdermal Parenteral Antiandrogens Spironolactone
Anticipated effects	Prevent secondary sexual characteristics of the assigned gender	Deepened voice Facial/body hair growth ↑ libido Amenorrhea Clitoral enlargement ↑ percentage muscle mass compared to body fat	Breast growth ↓ testicle size ↓ percentage muscle mass compared to body fat Antiandrogens may reduce effects of endogenous testosterone
Anticipated risks	May decrease BMD (may theoretically be reversed with sex hormone therapy)	Polycythemia Weight gain Acne Androgenic hair loss Sleep apnea	VTE Gallstones ↑ liver enzyme levels Weight gain Hypertriglyceridemia
No risk increase/ data inconclusive		BMD loss Breast cancer Cervical cancer Ovarian cancer Uterine cancer	Breast cancer

BMD = bone mineral density; FTM = female to male; GnRH = gonadotropin-releasing hormone; IM = intramuscular; MTF = male to female; SC = subcutaneous; VTE = venous thromboembolism.

as widely prescribed as data are limited regarding their use for puberty induction.

Serum testosterone levels are measured every 2 to 3 months to ensure that levels are in the normal physiologic range for males (320 to 1000 ng/dL). Importantly, the most common adverse effects of exogenous testosterone are erythrocytosis and more atherogenic lipid levels (Bhasin, 2006). Accordingly, patients undergo periodic laboratory testing while receiving treatment. Panels include a complete blood count (CBC), liver function tests (LFTs), and lipid and hemoglobin A_{1c} levels (Spack, 2013).

In male-to-female transgender individuals, feminizing therapy is often begun to promote breast growth, redistribute body fat, and reduce body hair growth. Estrogen, either conjugated equine estrogens or 17β-estradiol, is typically administered orally, transdermally, or parenterally (estrogen esters). Puberty induction with 17β-estradiol may begin with a 1-mg oral daily dose that is incrementally increased every 3 to 6 months to reach the typical adult maintenance doses of 4 to 6 mg daily. Similarly, transdermal estrogen may begin with a patch that delivers 0.1 mg/d estradiol daily and is changed once or twice weekly depending on brand. Dosing can then be incrementally raised to a daily 0.4 mg/d dose, which is achieved by wearing multiple 0.1 mg/d patches (Deutsch, 2018). As with any patient undergoing chronic estrogen replacement therapy, transgender women are screened and counseled regarding the higher risk for thromboembolic disease, liver dysfunction, and hypertension (Spack, 2013). Effects of hormone therapy and different methods of administration are summarized in Table 1-3.

Concurrently, testosterone is ideally lowered to premenopausal levels (<50 ng/dL). For this degree of suppression, treatment with estrogen alone is insufficient. Thus, adjuncts, such as progestins with antiandrogen activity or GnRH agonists, are options. Another is spironolactone, which directly blocks androgen receptor binding.

With therapy, serum testosterone and estradiol levels are measured every 3 months to ensure that serum estradiol levels do not exceed the peak physiologic range for premenopausal females. The preferred range is 100 to 200 pg/mL (Spack, 2013). Estrogen therapy can promote pituitary lactotroph cell growth. And, several reports describe prolactinomas occurring after long-term, high-dose estrogen therapy. Accordingly, periodic serum prolactin level testing is recommended (Hembree, 2017).

Surgical Management of Gender Dysphoria

Most, but not all, transgender individuals consider gender-affirming surgeries necessary to complete their transition. These procedures are classified as those that directly impair fertility and those that do not. The former include hysterectomy and gonadectomy, and in minors, performance of these is typically controlled by governing laws (Hembree, 2017). However, less-legislated procedures may be considered in both minors and

adults who have been living in their new gender role and have been receiving hormonal therapy for approximately 12 months. Such surgeries include mastectomy and breast reconstruction and other procedures meant to feminize or masculinize the face and body. Consensus among the patient, physician, and the mental health provider is advisable.

Female-to-male transgender individuals commonly choose total hysterectomy, and both vaginal and laparoscopic approaches are options. Of these, the vaginal approach appears to be more cost-effective and amenable to subsequent phalloplasty, which is creation of a phallus, if elected (O'Hanlan, 2007). The gynecologist also provides essential counseling regarding retention or removal of ovaries. This decision is made with utmost respect for the patient's autonomy and is directed by their desire for removal of their female gonads and their plans for future fertility. Gynecologic considerations also include comorbid pathology, such as endometriosis or positive *BRCA* gene mutation status, which may favor oophorectomy. As another counseling point, future disruption of their testosterone therapy due to financial constraints could pose osteoporosis risks from lack of exogenous steroid hormones. Primary ovarian retention may mitigate this risk.

During female-to-male transition, mastectomy is also often undertaken, as testosterone therapy has little effect on breast regression. In adults, discussion regarding mastectomy usually takes place after androgen therapy has begun. Other procedures available to transgender males have been less satisfactory and not as widely sought. Surgical creation of a neopenis is still cost-prohibitive and typically requires multiple stages. That said, newer surgical techniques are yielding improved cosmetic results (Monstrey, 2007).

Male-to-female transgender surgery can involve penile and testicular excision and creation of a neovagina. Postoperatively, significant risks for vaginal and urethral stenosis persist, and lifelong vaginal dilation is required to maintain neovagina patency. Other cosmetic procedures include breast augmentation and facial feminizing surgery. These reconstructive procedures are best performed by urologists, gynecologists, or plastic surgeons with experience and specialized training in this field.

Adolescent Care

The effects of gender dysphoria in adolescents are potentiated by the unwanted physical changes that accompany puberty. Medical treatment of gender dysphoria during puberty improves psychological functioning in this group (de Vries, 2011). The Endocrine Society suggests suppression of pubertal development in adolescents who meet criteria for gender dysphoria (Hembree, 2017).

Puberty suppression is commonly accomplished with gonadotropin-releasing hormone (GnRH) analogues in the form of the histrelin implant (Supprelin LA) or depot leuprolide acetate (Lupron). Histrelin is a single subcutaneous implant that delivers the GnRH agonist over 12 months. Depot leuprolide acetate is administered IM in distinct doses that supply activity for 1 month or for 3 months. With these agents, gonadotropin suppression is profound (Chap. 9).

Suppression is considered once Tanner stage 2 development is reached (Fig. 14-3), that is, before the physical signs of puberty have significantly progressed. GnRH agonists offer the advantage of complete reversibility. However, their overall effect on bone density is not well studied. Accordingly, the Endocrine Society recommends that bone mineral density testing be completed annually (Hembree, 2017). They also support initiation of gender-affirming hormones in adolescents by age 16, although use in 14-year-old adolescents has been described (de Vries, 2014).

Long-Term Considerations

Transgender aging is an underexplored field (Fredriksen-Goldsen, 2014). The American College of Obstetricians and Gynecologists (2018a) advocates against routine discontinuation of systemic hormone therapy in postmenopausal women if used for the management of persistent vasomotor symptoms. However, no such recommendations exist for gender-affirming hormones in transgender persons receiving long-term therapy.

Both testosterone and estrogen therapy pose many of the same medical risks in both trans- and cisgender populations. However, their use in transgender persons is complicated by prolonged exposure to exogenous high-dose hormones and the potential negative secondary effects of early gonadectomy. In addition to monitoring weight and blood pressure and directed physical examination, routine health evaluation should seek lifestyle risk factors (such as smoking) and concurrent use of medications that can heighten the risks of long-term gender-affirming hormone therapy. Laboratory testing described earlier is standard for transgender adults.

For transgender males, age-appropriate screening for breast cancer is continued as recommended by the American Cancer Society (Smith, 2018a). Long-term estrogen use does not raise the breast cancer risk in this group. But, breast cancer has been reported in transgender males even following mastectomy and highlights the need for continued screening (Shao, 2011). No cases of endometrial cancer have been reported in transgender males following long-term testosterone treatment. That said, individuals who maintain their uterus and ovaries are counseled regarding the potential risk of endometrial hyperplasia resulting from the aromatization of testosterone to estradiol (Futterweit, 1998; Moore, 2003). Thus, transgender males who present with abnormal uterine bleeding (AUB) following prolonged amenorrhea may benefit from evaluation similar to that in cisgender women with AUB. Evaluation for AUB may be considered if bleeding persists despite 6 to 12 months of suppressed luteinizing hormone and follicle-stimulating hormone levels and a testosterone level in the male range. If cervical tissue is still present, cervical cancer screening is performed as recommended by the American College of Obstetricians and Gynecologists (Chap. 29).

Transgender women should continue routine screening for prostate and breast cancer. Breast cancer has been reported in transgender females undergoing long-term estrogen therapy. That said, no long-term studies have determined the actual risk of breast cancer in this population (Ganly, 1995). Although the overall benefit of screening mammography for transgender females has not been established, breast cancer screening as in the general population is reasonable (Hembree, 2017).

Prolonged use of gender-affirming hormones has potentially negative effects on ovarian and testicular function. Thus, a discussion regarding plans for future childbearing is essential (Mayer, 2008). These discussions ideally take place prior to initiation of hormone therapy. Fertility preservation options offered to transgender individuals mirror those suitable to their cisgender counterparts (Chap. 21). Conversely, unintended pregnancies have occurred in transgender men receiving testosterone. Thus, contraceptive needs are addressed in patients who have maintained their uterus (Light, 2014). Contraceptive options for transgender men do not differ from those for cisgender women (Chap. 5). Testosterone is not a form of contraception, and this should be emphasized during patient discussion.

PREVENTIVE CARE

Gynecologists have an opportunity to evaluate their patients for leading causes of female morbidity and mortality and intervene accordingly. In 2016, screening recommendations by the American College of Obstetricians and Gynecologists (2016c) were updated. The USPSTF regularly revises its screening guidelines, which can be accessed at www.USPreventiveServicesTaskForce.org. Many of these topics are covered in other text chapters. Some remaining important subjects are presented in the following sections.

Immunization

The need for new or repeat administration of vaccines is best reviewed periodically. Table 1-4 summarizes recommended schedules, precautions, and contraindications for these adult vaccines, and as of 2019, a link is provided to the full schedules at: http://www.cdc.gov/vaccines/schedules. In general, any vaccine may be coadministered with another type at the same visit.

Cancer Screening

Colon Cancer

In the United States, colon cancer is the third leading cause of cancer death in women, behind lung and breast cancer (Siegel, 2019). Incidence and mortality rates from this cancer have declined during the past two decades, largely due to improved screening tools. No trials have directly compared any of the screening tools. Instead, identifying an acceptable screening strategy for an individual patient may improve overall compliance and screening completion rates (U.S. Preventive Services Task Force, 2016a).

Guidelines recommend screening average-risk patients for colorectal cancer from age 50 to 75 with any of the methods shown in Table 1-5 (Smith, 2018a). Black women in the United States have a higher incidence of colorectal cancer, and the U.S. Multi-Society Task Force on Colorectal Cancer recommends discussing initial screening at age 45 (Rex, 2017). Health care disparities related to race and colon cancer are complex, and patient-oriented outcome studies are lacking to strongly support this earlier screening. Other organization guidelines, including those of the USPSTF (2016a), have not yet supported this earlier screening age.

Direct visualization methods can detect cancer *and* precancerous lesions. Of these, colonoscopy visualizes the entire colon, and biopsy can be performed simultaneously if needed. Stool-based tests include fecal occult blood test, fecal immunochemical test, and stool DNA tests.

Because colonoscopy allows for both screening and simultaneous diagnostic evaluation, it is often the preferred colorectal cancer screening test. For the patient with average risk and normal findings, testing is repeated every 10 years. In the United States, the direct visualization method offered may depend on a patient's insurance plan coverage.

Fecal occult blood testing (gFOBT) is an adequate *annual* screening method when two or three stool samples are

TABLE 1-4. Summary of Recommendations for Adult Immunization

Vaccine and Route	Reason to Vaccinate	Vaccine Administration	Contraindications and Precautions[a,b]
Influenza[c] **IIV** *or* **RIV** *Give SC*	• All adults	• Yearly • October is ideal, or as long as virus is circulating	**Precaution** • GBS within 6 wk of prior vaccine • IIV: egg allergy
Pneumococcal **PCV13** *Give IM* **PPSV23** *Give IM or SC*	• All ≥65 yr • Chronic illness[d]; asplenia; immunocompromise; smokers	• Age ≥65 yr without health issues: PCV13, then PPSV23 after 1 yr ***or*** PPSV23, then PCV13 after 1 yr • Variant regimens for other indications[d]	
Hepatitis A *Give IM*	• Desires immunity • Contact or travel risk[e]; other health indications[d]	• Two doses: 0 and 6 months	
Hepatitis B *Give IM*	• Desires immunity • Contact or travel risks[e]; other health indications[d]	• Three doses: 0, 1, and 3 months	

(Continued)

TABLE 1-4. Summary of Recommendations for Adult Immunization *(Continued)*

Vaccine and Route	Reason to Vaccinate	Vaccine Administration	Contraindications and Precautions[a,b]
Combined Hepatitis A + B *Give IM*	• Indications for hepatitis A or B	• Three doses: 0, 1, and 6 months	
Tdap **Td** *Give IM*	• All adults • Pregnancy	• No prior vaccine: 1 dose Tdap • Td booster every 10 yr • At-risk wounds: booster Td dose if ≥5 yr since prior dose • Pregnancy: Tdap dose at 27–36 wk regardless of prior dosing	**Contraindication** • Tdap: encephalopathy after prior vaccine **Precaution** • GBS within 6 wk of prior vaccine • Tdap: unstable neurologic condition
Varicella *Give SC*	• Lacks immunity	• Two doses: 0 and 1 month • Nonimmune gravida: give series postpartum	**Contraindications** • Pregnancy • Immunocompromise **Precaution** • Recent antibody-containing blood products • Hold "-cyclovir" antivirals[f] 14 days after vaccine
Zoster **RZV** *Give IM* **ZVL** *Give SC*	• RZV: ≥50 yr ***or*** • ZVL: ≥60 yr	• Two doses: 0, 2–6 months • One dose	**ZVL Contraindications** • Immunocompromise • Pregnancy **Precaution** • Hold "-cyclovir" antivirals[f] 14 days after vaccine
MMR *Give SC*	• Lacks immunity	• One dose • Nonimmune gravida: give postpartum	**Contraindications** • Immunocompromise • Pregnancy **Precaution** • Prior thrombocytopenia • Recent antibody-containing blood products
HPV *Give IM*	• Desires immunity • Ages 9 to 45 yr	• Three doses: 0, 1, and 6 months	**Precaution** • Pregnancy

[a]Previous anaphylactic reaction to any of a vaccine's components serves as a contraindication for any vaccine.
[b]Moderate to severe illness is a precaution to vaccination. Mild illness is not a contraindication.
[c]Several influenza vaccines are available and listed at: https://www.cdc.gov/flu/protect/vaccine/vaccines.htm.
[d]Full guidelines found at http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.
[e]A list is found at https://wwwnc.cdc.gov/travel/page/yellowbook-home.
[f]These include acyclovir, famciclovir, valacyclovir.
GBS = Guillain-Barré syndrome; HPV = human papillomavirus; IIV = inactivated influenza vaccine; IM = intramuscular; MMR = measles, mumps, rubella; PCV = pneumococcal conjugate vaccine; PPSV = pneumococcal polysaccharide vaccine; RIV = recombinant influenza vaccine; RZV = recombinant zoster vaccine; SC = subcutaneous; Td = tetanus, diphtheria; Tdap = tetanus, diphtheria, activated pertussis; ZVL = zoster vaccine live.

TABLE 1-5. Screening Guidelines for the Early Detection of Colorectal Cancer and Adenomas for Average-Risk Women Aged 50 to 75 years[a]

Direct Visualization Tests		
Test	**Interval**	**Key Issues for Informed Decisions**
Colonoscopy	10 years	Bowel prep required; conscious sedation provided
FSIG	5 years	Bowel prep required, sedation usually not provided Positive findings usually merit colonoscopy
CT Colonography	5 years	Bowel prep required, polyps ≥6 mm merit colonoscopy; incidental extracolonic findings are common and can result in unnecessary diagnostic testing
Stool-based Tests		
Test	**Interval**	**Key Issues for Informed Decisions**
gFOBT	Annually	Two to three stool samples *collected at home* (a single sample gathered during an office examination is insufficient); positive results merit colonoscopy
FIT	Annually	Single specimen *collected at home*; positive results merit colonoscopy
FIT-DNA	3 years	Lower specificity/higher sensitivity than FIT; positive results merit colonoscopy

[a]One method is selected.
FIT = fecal immunochemical test; FSIG = flexible sigmoidoscopy; gFOBT = guaiac-based fecal occult blood test.
Adapted from Rex, 2017; Smith, 2018a; U.S. Preventive Services Task Force, 2016a.

self-collected by the patient and the cards are returned for analysis. This method relies on a chemical oxidation reaction between the heme moiety of blood and alpha guaiaconic acid, a component of guaiac paper. However, gFOBT is not specific for human blood, and some factors can yield false-positive results. Ingestion of red meat or iron is an example. In contrast, vitamin C may preemptively react with the reagents and lead to false-negative results (Park, 2010). All of these must be eliminated for 3 days before testing. In addition, women should avoid nonsteroidal antiinflammatory drugs (NSAIDs) 7 days prior to testing to limit risks of gastric irritation and bleeding. These restrictions are cumbersome for some patients and lead to noncompliance.

Alternatively, the fecal immunochemical test (FIT) relies on an immune reaction to human hemoglobin. Similar to gFOBT, the FIT test is performed for annual screening on patient-collected stool samples but does not require pretesting dietary limitations. Advantages to FIT include greater specificity for human blood, and thus fewer false-positive results and improved accuracy for detecting colorectal cancer (U.S. Preventive Services Task Force, 2016a). An emerging screening strategy combines FIT with testing for altered DNA biomarkers in cells shed into the stool (FIT-DNA). One Food and Drug Administration (FDA)-approved test, Cologuard, screens stool for both DNA and hemoglobin biomarkers that are associated with colorectal cancer (Imperiale, 2014). Positive test results from any of these three stool tests warrant further evaluation by colonoscopy.

During patient evaluation of pelvic complaints such as pain, a gynecologist not uncommonly performs gFOBT testing for diagnostic purposes on a single stool sample obtained during digital rectal examination. As noted, this single stool sample is not adequate colorectal cancer screening.

These guidelines are appropriate for those with average risk. High-risk factors include a personal history of colorectal cancer or adenomatous polyps, a first-degree relative with colon cancer or adenomas, chronic inflammatory bowel disease, prior cancer-related abdominopelvic radiation, or known or suspected hereditary syndrome such as hereditary nonpolyposis colon cancer (Lynch syndrome) or familial adenomatous polyposis (Smith, 2018a).

Lung Cancer

In the United States, this cancer is estimated to account for 13 percent of all new cancers diagnosed in women in 2019 (Siegel, 2019). It is now the leading cause of cancer-related death in both men and women. Cumulative exposure to tobacco smoke is an important risk factor for lung cancer; thus all smokers should be advised of tobacco-use risks and encouraged to stop. A list of potential aids is described later.

Lung cancer screening with low-dose computed tomography (CT) scanning is recommended for individuals aged 55 to 74, who have a 30-pack-year or longer history, who actively smoke or quit within the past 15 years, and who lack life-limiting comorbidities (Tanoue, 2015). One remembers that pack-year determination is calculated by multiplying the number of packs smoked per day by the number of years the person has smoked. By convention, one pack contains 20 cigarettes. Although a common diagnostic test, chest radiography is not recommended as a lung cancer screening tool.

Skin Cancer

The incidence of skin cancers (melanoma and non-melanomas) has risen in the United States during the past three decades. In 2019, melanoma was expected to account for 1 percent of all cancer deaths in women (Siegel, 2019). Skin cancer risks

include fair complexion, use of indoor tanning beds, history of sunburns, family or personal history of skin cancer, and personal history of numerous moles (>100). The USPSTF (2016b) notes insufficient evidence to recommend whole body screening by physician or patient for skin cancer in the general adult population. It does advise clinicians to use the "ABCDE" system—asymmetry, border irregularity, color, diameter (>6 mm), and evolving over time—to evaluate skin lesions of concern and refer appropriately.

Lifestyle Changes

Smoking

Tobacco use is the leading preventable cause of disease, disability, and death in the United States and has been linked with certain cancers, cardiovascular disease, chronic lung diseases, and stroke (Barboza, 2016). Moreover, specific to women's health, smoking is linked to diminished fertility, pregnancy complications, and postoperative complications.

Almost 70 percent of adults who smoke daily are interested in quitting, and approximately half attempted to quit in the previous year. Guidelines from the USPSTF recommend that clinicians ask all patients about tobacco use, advise them to stop, and provide brief behavioral interventions (Siu, 2015a).

Behavioral interventions can be effective for any health-related lifestyle change. The five A's framework is a useful strategy for engaging patients and is tailored for smoking cessation in this example.

- Ask: every patient about tobacco use
- Advise: all users to quit
- Assess: her willingness to quit and decide if she is in a (1) precontemplation, (2) contemplation, (3) preparation, or (4) action phase. Her stage of readiness guides further discussion
- Assist: her attempts to quit (develop plan together)
- Arrange: for follow-up

Many behavioral interventions are available including local or community group programs, brief in-person behavioral counseling sessions, or even telephone counseling interventions. Patients can be referred to the National Cancer Institute's smoking cessation website: www.smokefree.gov or toll-free quit line: 1-800-QUIT-NOW. These supports provide free, evidence-based information, professional assistance, and in some cases free or discounted cessation medications.

Pharmacotherapy interventions approved by the FDA are bupropion SR, varenicline, and nicotine replacement therapy. These can be used in combination with behavioral interventions, and their use together can improve cessation rates. If appropriate, pharmacologic treatments to aid smoking cessation can be offered to all interested women and are listed in Table 1-6. Gynecologists who are proficient in the use of these therapies may prescribe. Referral is also appropriate (American College of Obstetricians and Gynecologists, 2014).

Exercise

Exercise is known to help prevent coronary artery disease, diabetes, osteoporosis, obesity, depression, insomnia, and multiple types of cancer (Piercy, 2018). Many of these associations result from the effects of exercise to help lower blood pressure, improve blood sugar control, reduce weight, and decrease low-density lipoprotein (LDL) cholesterol levels (Eckel, 2014).

In 2018, an estimated 10 percent of the premature mortality rate was associated with inadequate physical activity (Piercy, 2018). Recommendations from the U.S. Department of Health and Human Services (2018) include moderate-intensity activity for at least 150 minutes each week *or* vigorous-intensity activities for 75 minutes each week. When counseling patients on physical activity, the "talk test" is helpful to determine activity intensity. Generally, a woman doing moderate-intensity aerobic exercise can talk, but not sing, during the activity. A person doing vigorous-intensity activity generally cannot say more than a few words without pausing for a breath. Current evidence also supports raising routine daily physical activity levels, such as taking the stairs rather than the elevator (Piercy, 2018).

Research supports biweekly muscle-strengthening exercise that involves all the major muscle groups. Sedentary behavior, specifically time spent sitting, has also become of interest. Guidelines are beginning to address risks, but no recommendations are currently available.

Obesity

Associated Risks and Diagnosis

In 2016, 40 percent of women in the United States were obese, and this reflects a steady rise over the previous decade (Hales, 2018). Possible consequences include diabetes mellitus, nonalcoholic fatty liver disease, hypertension, hyperlipidemia, heart disease, osteoarthritis, and obstructive sleep apnea. Gynecologic issues related to obesity include abnormal menstruation, risks for endometrial neoplasia, and worsening polycystic ovary syndrome. Some hormonal contraceptives and emergency contraceptives may have lower efficacy in obese women. And, during pregnancy, obese women suffer higher rates of cesarean delivery, gestational diabetes, preeclampsia, and postpartum hemorrhage, among others (Hawkins, 2018). Even if not trained as weight management specialists, clinicians ideally screen for obesity, provide initial obesity evaluation and management, and refer as needed.

Screening is accomplished with calculation of body mass index (BMI). BMI, although not a direct measure of body fat content, is valuable in assessing the risk for weight-related complications. Several online calculators can be found. For adolescents (and children), BMI is adjusted for age and gender and calculated as a percentile. A BMI calculator for adolescents can be found at http://apps.nccd.cdc.gov/dnpabmi/.calculator.aspx. Table 1-7 reflects the definitions for underweight, overweight, and obesity for adolescents and adults. Adult obesity is further divided. Class 1 is a BMI 30 to 34.9 kg/m^2, class 2 is 35 to 39.9 kg/m^2, and class 3 is ≥40 kg/m^2. Class 3 obesity is often referred to as extreme obesity.

No standard single or panel laboratory test is indicated for an obese woman. Evaluation for comorbidities is tailored and factors her family and social histories. Blood pressure measurement, fasting lipid and glucose level screening, and thyroid function testing can all be considered for these patients during initial evaluation.

TABLE 1-6. Drugs Used for Smoking Cessation

Agent	Brand Name	Initial Dosing	Maintenance	Therapy Duration	Additional Considerations
Nicotine Replacement					
Patch[d]	Habitrol Nicoderm CQ	If >10 CPD: a 21-mg patch is reapplied daily wk 1–6 If <10 CPD: 14-mg patch for wk 1–6	14-mg patch is used wk 7–8	8–12 wk	
Gum[d]	Nicorette 2 mg 4 mg (if ≥25 CPD)	1 piece every 1–2 hr for wk 1–6 (maximum 24 pieces/d)	1 piece every 2–4 hr for wk 7–9	12 wk	Not chewed like regular gum, "chew and park" Not for those with extensive dental work
Lozenge[b]	Commit 2 mg 4 mg (if smokes <30 min after waking)	1 piece every 1–2 hr for wk 1–6 (maximum 20 pieces/d)	1 piece every 2–4 hr for wk 7–9	12 wk	Do not eat 15 min prior
Inhaler[d]	Nicotrol		6 (average use) to 16 cartridges puffed qd for 12 wk	12–24 wk	More expensive
Nasal spray[d]	Nicotrol		1 dose = 1 spray to each nostril per hr (maximum 5 doses/hr & 40/d)	12–24 wk	More expensive
Nicotine Agonists					
Varenicline[c]	Chantix	0.5 mg PO qd for 3 d, then 0.5 mg PO bid for next 4 d	1 mg PO bid	12 wk	Start 1 wk before quit date Avoid if history of suicide ideation or attempt; nausea is common
CNS Agents					
Bupropion[c]	Wellbutrin SR Zyban	1–2 wk prior to cessation: 150 mg PO qd for 3 d	150 mg PO bid	7–12 wk; may use for 6 mo.	Start 1 wk before quit date Avoid in patients with disordered eating, seizures, insomnia
Nortriptyline[a,d]		25 mg PO qd with gradual increase	75–100 mg PO qd	12 wk; may use for 6 mo.	Start at least 10 d before quit date
Clonidine[a,c]	Catapres-TTS	0.1-mg transdermal patch is changed weekly	0.1- to 0.2-mg transdermal patch weekly		Use limited by: dry mouth, sedation, postural hypotension

[a]Recommended as second-line agents by U.S. Department of Health and Human Services (Fiori, 2008).
[b]Has not been evaluated by the Food and Drug Administration (FDA) for pregnancy.
[c]Considered an FDA pregnancy category C drug.
[d]Considered an FDA pregnancy category D drug.
bid = twice daily; CNS = central nervous system; CPD = cigarettes per day; PO = orally; qd = daily.

TABLE 1-7. Definitions of Abnormal Weight for Adults and Adolescents Using Body Mass Index

Age Group	Underweight	Overweight	Obese		Extreme Obesity
Adolescent	<5th percentile for age	85th to 95th percentile for age	>95th percentile for age		
Adult	<18.5	25–29.9	Class I: 30–34.9	Class 2: 35–39.9	Class 3: ≥40

For a woman with an elevated BMI, a clinician assesses her readiness for change and thereby, provides appropriate guidance, support, or referral. In addition, questions regarding previous attempts at weight loss, social hurdles that impede diet and exercise change, and detrimental eating habits are discussed.

Treatment

Effective weight loss is best achieved by assisting patients in making healthier dietary, physical activity, and behavioral choices that will lead to a net negative caloric balance. The initial goal is to achieve a 5 to 10 percent weight loss over the initial 6 months of treatment (Jensen, 2014; National Heart, Lung, and Blood Institute, 2013). Caloric reduction is the most important component, whereas increased and sustained physical activity is particularly important in maintenance. Table 1-8 illustrates recommended guidelines to direct therapy for overweight or obese women. Several clinician and patient aids can be found in *Managing Overweight or Obesity in Adults*, available at: www.nhlbi.nih.gov/health-topics/managing-overweight-obesity-in-adults.

One of the most effective strategies encourages self-monitoring with a diet/activity calorie tracker. Many free versions are accessible either online or through smartphone applications. One sponsored by the U.S. Department of Agriculture is available at: www.choosemyplate.gov. Women are encouraged to follow a low-calorie diet that yields a 500 kcal/d deficit. This is an intake of 1200 to 1500 kcal/d (Jensen, 2014; National Heart, Lung, and Blood Institute, 2013). Specific daily calorie requirements by gender and age from the Institute of Medicine (2002) are listed at: www.health.gov/dietaryguidelines/2015/guidelines/appendix-2/.

In addition to diet and exercise, pharmacologic or surgical options may be advised for selected obese patients. Table 1-9 outlines specifics of weight loss medications. Orlistat (Xenical) is a reversible inhibitor of gastric and pancreatic lipases and blocks the digestion and absorption of approximately 30 percent of dietary fat (Kushner, 2018). This drug is approved for over-the-counter use at half the prescription strength (Alli). Because of its action, fatty stools and increased defecation are common side effects. Severe liver injury has been reported rarely, and labeling reflects this risk (Food and Drug Administration, 2010). Orlistat can reduce the absorption of fat-soluble vitamins, and patients are advised to take a daily oral multivitamin (Bray, 2013). Combination oral contraceptive action is not reduced by orlistat (Hartmann, 1996). This agent is not recommended during pregnancy but does not appear teratogenic (Källén, 2014). Orlistat is poorly absorbed, and thus theoretically is unlikely to reach significant breast milk levels (Briggs, 2017).

Four medications have been approved by the FDA since 2012: lorcaserin, phentermine-topiramate, naltrexone-bupropion, and liraglutide. Each suppresses appetite, and all are approved in conjunction with a reduced-calorie diet. These medications have met stringent FDA requirements, which included predetermined measures of effectiveness (5 percent mean weight loss after 1 year) and postmarketing long-term cardiovascular disease outcome trials (Kushner, 2018). The FDA recommends evaluation of weight loss after 3 to 4 months. This is based on observations that those who fail to lose weight early are less successful at 1 year. Choice of a specific agent is individualized and may be driven by comorbidities. For example, liraglutide might be more appropriate for a woman with diabetes (Khera, 2016). None of these are recommended during pregnancy or lactation.

Lorcaserin is a serotonin-receptor agonist used to suppress appetite. Naltrexone SR-bupropion SR (Contrave) is a combination of naltrexone, which is FDA approved for the treatment of alcohol dependence and opioid blockade, and bupropion, an antidepressant and smoking cessation aid.

Phentermine-topiramate (Qsymia) is a combination medication and is gradually titrated upward as needed. This drug has fetotoxicity potential and prescribing providers must participate in a Risk Evaluation and Mitigation Strategy (REMS) program. REMS are safety strategies mandated by the FDA to help manage known risks associated with a medicine yet still allow patients to have access to the benefits of a given drug.

Liraglutide is a glucagon-like peptide-1 receptor agonist delivered by self-administered subcutaneous injection. In studies, mean

TABLE 1-8. Treatment Recommendations According to BMI

Treatment	BMI 25–26.9	BMI 27–29.9	BMI 30–34.9	BMI 35–39.9	BMI ≥ 40
Diet, activity, behavioral therapy	WCM	WCM	+	+	+
Pharmacotherapy	—	WCM	+	+	+
Surgery	—	—	—	WCM	+

+ represents the use of indicated treatment regardless of comorbidities; BMI = body mass index; WCM = with comorbidities (type 2 DM, hypertension, obstructive sleep apnea, heart disease).

TABLE 1-9. Drugs Used for Weight Loss

Agent (Brand Name)	Oral[a] Daily Dosing	Mechanism	Placebo-subtracted Wt. Loss at 1 Year (%)	Adverse Effects
Gastrointestinal Fat Blocker				
Orlistat (Xenical, Alli)	120 mg three times	Blocks digestion and absorption of fat	n/a (6.2 kg avg. wt. loss)	Oily stools, fecal urgency or fecal incontinence
Appetite Suppressant				
Lorcaserin (Belviq)	10 mg twice	Serotonin receptor agonist	3.2	Headache, dizziness, increased heart rate or blood pressure
Phentermine/ topiramate (Qsymia)	3.75 mg/23 mg once for 2 wks, then 7.5 mg/46 mg once for 12 wks	Similar to amphetamines, appetite suppressed and satiety enhanced	8.4	Paraesthesia, dizziness, dysgeusia, insomnia, constipation, dry mouth
Naltrexone/bupropion (Contrave)	8 mg/90 mg (1 tab); titrate up by 1 tab each wk to reach 2 tabs twice daily	Opioid antagonist, antidepressant	4.0	Headache, GI side effects, insomnia, dry mouth
Liraglutide (Saxenda)	0.6 mg SC; titrate up by 0.6 mg SC each wk to reach 3 mg SC once daily	GLP-1 agonist, slows gastric emptying, decreases food intake	5.0	GI side effects

[a]Except for liraglutide.
GI = gastrointestinal; GLP-1 = glucagon-like peptide-1 receptor agonist; n/a = not available; SC = subcutaneously; Wt. = weight.

weight loss averages 6 to 8 percent (Davies, 2015; Pi-Sunyer, 2015). Liraglutide has an associated risk for pancreatitis. Because of this and an unclear risk of medullary thyroid carcinoma, the FDA requires participation in a REMS program. This drug is contraindicated for women with a family or personal history of medullary thyroid carcinoma or multiple endocrine neoplasia (Novo Nordisk, 2017).

Bariatric surgery is an important consideration for women with BMIs ≥40 or with BMIs ≥35 if other comorbid conditions are present (Garber, 2018). Of available laparoscopic procedures, three are more commonly performed and fall into two categories: restrictive (gastric banding, gastric sleeve) or malabsorptive (gastric bypass). Gastric banding places an adjustable plastic ring around the stomach to limit food intake. Sleeve gastrectomy removes 80 percent of the body of the stomach, creating a tubular sleeve appearance. Restrictive procedures produce modest weight loss and carry low surgical complication rates (Wolfe, 2016).

The Roux-en-Y gastric bypass creates a small stomach pouch that is connected directly to the jejunum to bypass the duodenum. This reduces calorie and nutrient absorption and can lead to substantial weight loss in individuals with morbid obesity. Gastric bypass has been linked with improvement in comorbid risk factors and decreased mortality rates. However, common long-term problems can include malabsorption of micronutrients such as iron, folate, calcium/vitamin D, and vitamin B_{12} (Abdeen, 2016).

Following bariatric surgery, patients are advised to delay pregnancy for 12 to 24 months (American College of Obstetricians and Gynecologists, 2017a). Rapid weight loss during this time poses theoretical risks for intrauterine fetal-growth restriction and nutritional deprivation. However, as weight is lost, fertility rates overall appear to improve, and risks for pregnancy rise (Merhi, 2009). Thus, effective contraception is needed. Most contraceptive methods appear to be as effective in women with elevated BMIs compared with normal-weight controls. However, the contraceptive patch (OrthoEvra) is less effective in those weighing more than 90 kg (Zieman, 2002). Specific to those with malabsorptive bariatric surgery types, oral contraception efficacy may be lower due to poor absorption (Curtis, 2016). Last, due to its risk for associated weight gain, depot medroxyprogesterone acetate (Depo-Provera) may be an unpopular choice in women trying to lose weight.

Cardiovascular Disease

This is the leading cause of death in the United States. In 2011 to 2014, 36 percent of women were affected by cardiovascular disease (CVD), and more than 410,000 women died from its complications (Benjamin, 2018). Stratification of CVD predispositions can identify vulnerable patients for management or referral (Table 1-10). Ideal goals for exercise, glucose and lipid levels, blood pressure, and smoking cessation are discussed in other sections of this chapter.

TABLE 1-10. Classification of Cardiovascular Disease (CVD) in Women

≥1 assigns high-risk status	Known CHD or CVD Peripheral arterial disease Abdominal aortic aneurysm End-stage renal disease Diabetes mellitus
≥1 assigns at-risk status	Smoking SBP ≥120 or DBP ≥80 mm Hg, or treated hypertension Total cholesterol ≥200 mg/dL, HDL <50 mg/dL, or treated dyslipidemia Obesity Poor diet Physical inactivity Family history of premature CVD Metabolic syndrome Autoimmune collagen-vascular disease Prior PIH or gestational DM

CHD = coronary heart disease; CVD = cardiovascular disease; DBP = diastolic blood pressure; DM = diabetes mellitus; HDL = high-density lipoprotein; PIH = pregnancy-induced hypertension; SBP = systolic blood pressure.
Abbreviated from Mosca, 2011.

Chronic Hypertension

Nearly 45 million American women are hypertensive, and this accounted for 33 percent of U.S. women from 2011 to 2014. The risk of hypertension rises with age and is higher for black women compared with those of other races (Benjamin, 2018). Chronic hypertension raises the risks for myocardial infarction, stroke, congestive heart failure, renal disease, and peripheral vascular disease. Moreover, chronic hypertension and its potential therapies may limit contraception choices for some women. Thus, gynecologists ideally are familiar with criteria used to diagnose hypertension. Although many may choose to refer patients for hypertension treatment, gynecologists should be aware of target goals and long-term risks associated with this disease.

For adult screening, the American Heart Association (2017) recommends blood pressure assessment starting at age 20 and repeated evaluation every 2 years if initially normal (Table 1-11). For patients with elevated pressures, assessment is at least annually.

With screening, blood pressures are best taken with a woman seated in a chair with the tested arm resting on a table, at the level of the heart. Ideally, the patient has been able to rest quietly for a few minutes prior to measurement and to have refrained from tobacco and caffeine use immediately prior to testing. An appropriately sized cuff is selected, and the cuff bladder should encircle at least 80 percent of the arm. Hypertension is diagnosed if readings are elevated on at least two separate office visits over one or more weeks.

With the diagnosis of chronic hypertension, assessment then follows for both modifiable and nonmodifiable CVD risk factors. Thus, routine laboratory tests recommended before initiating therapy include an electrocardiogram, urinalysis, blood glucose level, complete blood count, lipid profile, thyroid testing, and serum potassium and creatinine level measurement. A more extensive search for identifiable underlying causes is not generally indicated unless hypertension is not controlled with initial treatment (Table 1-12) (Whelton, 2018).

For treatment, lifestyle changes that mirror those for CVD are encouraged. However, if blood pressure is significantly elevated or resistant to lifestyle modification alone, then pharmacologic treatment may be needed to decrease long-term complications. Recommendations are shown in Table 1-13, and the target blood pressure with treatment is <130/80 mm Hg.

TABLE 1-11. Blood Pressure Categories in Women

BP Category	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80
Elevated	120–129	and	<80
Stage 1 HTN	130–139	or	80–89
Stage 2 HTN	>140	or	>90

DBP = diastolic blood pressure; HTN = hypertension; SBP = systolic blood pressure.
Adapted from Whelton, 2018, with permission.

Stroke

This is the fifth leading cause of death in the United States, and in 2014, approximately 425,000 American women suffered a new or recurrent stroke (Benjamin, 2018). Gender-specific risk

TABLE 1-12. Identifiable Causes of Hypertension

Common	Renal parenchymal disease Renovascular disease Primary aldosteronism Obstructive sleep apnea Drug/alcohol Caffeine Smoking Alcohol NSAIDs Oral contraceptives Cyclosporine Decongestant/anorectics Herbal medicines (ephedra, ma huang) Cocaine and amphetamines Adrenal steroids
Uncommon	Pheochromocytoma Thyroid or parathyroid disease Cushing syndrome Coarctation of the aorta Congenital adrenal hyperplasia

NSAIDs = nonsteroidal antiinflammatory drugs.

TABLE 1-13. Initial Drug Therapy for Adults with Hypertension

Health Status	Treatment
General	Nonblack: thiazide-type diuretic, ACEI, ARB, or CCB Black: thiazide-type diuretic or CCB
Renal disease	ACEI or ARB

ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; BP = blood pressure; CCB = calcium-channel blocker.

factors for stroke in women include hypertension, atrial fibrillation, migraines with aura, and combination oral contraceptives. Low-dose aspirin use for the primary prevention of CVD is recommended only in women aged 50 to 59 years who have a ≥10 percent CVD risk (using the risk calculator outlined next) and are not at increased risk for bleeding (Bibbins-Domingo, 2016). No consensus describes the optimal dose or frequency of aspirin for stroke prevention. For women aged ≥60, the conversation balances risks of bleeding complications from aspirin against the benefits of stroke prevention for a given patient.

Dyslipidemia

Hypercholesterolemia

Serum cholesterol is known to be related to atherosclerotic CVD (ASCVD). The lipoprotein carriers are LDL, high-density lipoprotein (HDL), and very low-density lipoprotein (VLDL), and LDL is the dominant atherogenic form (Grundy, 2018). Other ASCVD risk factors include smoking, hypertension, dysglycemia, and advancing age. Using these, prediction models can estimate the risk of developing ASCVD. One tool is available through a smartphone application or accessible online at www.tools.acc.org/ASCVD-Risk-Estimator-Plus.

Preventively, adults aged ≥20 years ideally have lipids measured (either fasting or nonfasting) every 5 years. This profile includes measurement of total, LDL, and HDL cholesterol levels and triglyceride concentrations. If the initial nonfasting lipid profile reveals a triglycerides level ≥400 mg/dL, a fasting lipid is then performed (Grundy, 2018).

Lowering LDL levels is associated with reduced rates of ASCVD. Initial management usually begins with lifestyle and dietary changes. Lipid-lowering treatment for primary prevention is added for: (1) those with persisting LDL levels ≥190 mg/dL, (2) those aged 40 to 75 years with diabetes and LDL levels ≥70 mg/dL, and (3) those aged 40 to 75 years with an estimated 10-year risk of a cardiovascular event that is at least 7.5 percent (Stone, 2014). The risk estimator referenced above can help guide providers through recommendations and offer therapeutic advice.

Hypertriglyceridemia

Triglycerides are not directly atherogenic. Instead, they represent an important biomarker of CVD risk because of their association with proinflammatory, proatherogenic proteins found on all classes of the plasma lipoproteins. Because hypertriglyceridemia is associated with many other unique CVD risk factors, the benefit of lowering triglycerides directly remains uncertain (Jellinger, 2017). Triglycerides are particularly responsive to dietary adjustments, specifically restricting fat and carbohydrates. Omega-3 supplementation can also help lower levels. Medication therapy is reserved for those with triglyceride levels ≥500 mg/dL and is implemented to lower these levels to prevent pancreatitis.

Diabetes Mellitus

Diabetes is common, and approximately 14.9 million adult women in the United States are diabetic (Centers for Disease Control and Prevention, 2017a). The long-term consequences of this endocrine disorder are serious and include coronary heart disease, stroke, peripheral vascular disease, nephropathy, neuropathy, and retinopathy.

The USPSTF recommends screening of all adults aged 40 to 70 who are overweight or obese (Siu, 2015b). However, the American Diabetes Association (2019) recommends that screening be considered at 3-year intervals in those aged ≥45 or in those with a BMI ≥25 and one other risk factor (Table 1-14).

Diabetes and prediabetes may be diagnosed by various laboratory tests listed in Table 1-15. Measurement of plasma glucose concentration is performed on venous samples, and the aforementioned values are based on the use of such methods. Capillary blood glucose testing using a blood glucometer is an effective monitoring tool but is not recommended for diagnostic use.

For those diagnosed with diabetes, referral to an internist is usually indicated. Control of blood glucose levels reduces microvascular complications such as CVD, neuropathy, and nephropathy. Lifestyle optimization is essential for all patients with diabetes, and weight loss is recommended for overweight or obese patients with prediabetes or diabetes mellitus type 2. If lifestyle modification is insufficient for glucose control, many therapeutic options are available for patients in lieu of insulin. To lower diabetic morbidity, therapy goals for otherwise normal patients include hemoglobin A_{1c} levels below

TABLE 1-14. Adult Risk Factors for Diabetes

Age ≥45 years
Body mass index ≥25
Affected first-degree relative
Physical inactivity
Ethnicity: African-, Hispanic-, Native-, and Asian-Americans; Pacific Islanders
Prior prediabetes-range test values
Prior gestational diabetes mellitus
Hypertension (≥140/90 mm Hg or on therapy)
HDL cholesterol <35 mg/dL and/or triglyceride level >250 mg/dL
Polycystic ovary syndrome
Acanthosis nigricans
Cardiovascular disease

HDL = high-density lipoprotein.

TABLE 1-15. Diagnostic Criteria for Diabetes Mellitus

HbA_{1C} ≥6.5%
or
Fasting plasma glucose ≥126 mg/dL. Fasting is no caloric intake for at least 8 hr
or
2-hr plasma glucose ≥200 mg/dL during an OGTT
or
Symptoms of diabetes plus random plasma glucose concentration ≥200 mg/dL. Classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss

Criteria for Increased Diabetes Risk (prediabetes)
Fasting plasma glucose: 100–125 mg/dL
or
2-hr plasma glucose during 75-g OGTT: 140–199 mg/dL
or
HbA_{1C}: 5.7–6.4%

FPG = fasting plasma glucose; HbA_{1c} = hemoglobin A_{1c}; OGTT = oral glucose tolerance test.

6.5 percent, blood pressure readings <130/80 mm Hg, LDL levels <100 mg/dL, triglyceride levels <150 mg/dL, weight control, and smoking cessation (Garber, 2018).

Patients with prediabetes, that is, impaired fasting glucose or impaired glucose tolerance, have an elevated risk for developing diabetes. To avert or delay this, management includes greater physical activity and weight loss, drugs such as metformin, nutritional counseling, and yearly diabetes screening. Medications, including weight loss medications discussed earlier, can be considered for those meeting criteria.

Metabolic Syndrome

The metabolic syndrome refers to a clustering of specific CVD risk factors with the underlying pathophysiology thought to be related to insulin resistance (Grundy, 2005; Kahn, 2005). The components include insulin resistance, visceral obesity, hypertension, and low HDL but high triglyceride levels.

When the metabolic syndrome was initially identified, it served as a useful paradigm to draw attention to the fact that CVD risk factors often clustered in patients. Over time, as risk assessments and screening guidelines have advanced, the clinical usefulness of the metabolic syndrome has waned. If identified, management of the syndrome does not differ from management of individual risk factors and focuses on lifestyle modification discussed in earlier sections.

Thyroid Disease

The risk of thyroid disease accrues with age, and dysfunction is more common in women. Expert panels disagree regarding thyroid screening of the general population. Only the American Thyroid Association recommends that adults, especially women, be screened for thyroid dysfunction by measurement of a serum thyroid-stimulating hormone (TSH) concentration, beginning at age 35 and then again every 5 years. Other organizations' guidelines recommend screening in older women or those with risk factors for thyroid disease (LeFevre, 2015). People at higher risk include the elderly and those with prior head or neck radiation, thyroid surgery, autoimmune disease, type 1 diabetes mellitus, affected first-degree relative, pituitary disease, or lithium use.

Geriatric Screening

Women are now living longer, and the current life expectancy for women in the United States is 81 years (Arias, 2017). As a woman moves past menopause, many of her health care needs may not be gynecologic.

Of these, functional status is a patient's ability to perform both basic and complex activities for independent living. Basic activities are grooming and toileting, whereas bill paying and housekeeping are more complex instrumental activities of daily living (Katz, 1963; Lawton, 1969). Declines in functional status are linked to higher risks of hospitalization, institutionalization, and death. Identifying this status loss may permit early intervention.

Loss of cognitive function may present as short- and long-term memory loss, difficulty with problem solving, or inattention to personal hygiene. Although not expert in the diagnosis of cognitive problems, a gynecologist can perform initial screening that either reassures or prompts more formal evaluation by a geriatrician or neurologist. During Medicare Annual Wellness Visits (AWV), cognitive evaluation is a mandatory component.

For screening purposes, the test choice ideally matches the level of concern. For patients in whom cognitive impairment is thought unlikely, the clock-drawing test can provide reassurance. For this test, a person is asked to draw a clock with "the hands set to 10 past 11." A correct clock has numbers 1 through 12 labeled correctly in a clockwise fashion, with two arms (of any length) pointing at the correct numbers for the time requested. Any error or refusal to complete the clock is considered abnormal.

The Mini-Cog Test can also screen for mild cognitive impairment in the primary care setting (Janssen, 2017). The Mini-Cog test requires approximately 3 minutes to administer and begins by giving the patient three items to remember early in the interview. Later in discussion, she is asked to recall those three items. For a Mini-Cog Test result suggestive of dementia, referral to an internist, geriatrician, or neurologist is indicated.

Last, in those for whom impairment is a possibility, the Montreal cognitive assessment (MOCA) can be used to screen (Nasreddine, 2005). This tool assesses different cognitive domains and may characterize a cognitive impairment more precisely than the clock or Mini-Cog tests.

Mental Health

Depression

For women of all ages, mood disorders are pervasive and account for significant morbidity and mortality. These are discussed in detail in Chapter 14 and should be screened for during routine health visits.

TABLE 1-16. Insomnia Medications Approved by the U.S. Food and Drug Administration

Medication: Brand	Dose
Benzodiazepines	
Temazepam: Restoril	7.5–30 mg
Estazolam: ProSom	0.5–2 mg
Triazolam: Halcion	0.125–0.25 mg
Flurazepam: Dalmane	15–30 mg
Quazepam: Doral	7.5–15 mg
Benzodiazepine-receptor Agonists	
Eszopiclone: Lunesta	1–3 mg
Zolpidem: Ambien,	5–10 mg
Ambien CR[a]	6.25–12.5 mg
Intermezzo[b]	1.75 mg
Zaleplon: Sonata	5–20 mg
Melatonin-receptor Agonist	
Ramelteon: Rozerem	8 mg
Melatonin-receptor Agonist	
Doxepin: Silenor	3–6 mg
Dual Orexin-receptor Antagonist	
Suvorexant: Belsomra	5–20 mg

[a]Extended release form.
[b]Indicated for middle-of-night awakening.

For depression, the Personal Health Questionnaire-2 (PHQ2) is a simple, two-question screening tool (Kroenke, 2003). Questions are: "During the past 2 weeks, have you felt down, depressed, or hopeless?" and "Have you felt little interest or pleasure in doing things?" A positive screening result should prompt evaluation for depression (Chap. 14).

Insomnia

Insomnia is common. It is defined as trouble initiating or maintaining sleep, despite adequate opportunity and circumstances for sleep, and is associated with daytime consequences (Sateia, 2017). Insomnia may be primary or may be secondary to other conditions such as depression, restless leg syndrome, stimulant use, menopause symptoms, and sleep apnea (Baker, 2018).

Insomnia is typically treated first with cognitive-behavioral therapy (CBT) (Sateia, 2017). Cognitive therapy is aimed at changing patients' beliefs and attitudes regarding sleep. Components include control of sleep timing and duration, attempts to improve the bedroom environment, or relaxation or biofeedback techniques. Medications may be added to aid sleep, and many work via benzodiazepine receptors. Table 1-16 lists medications FDA-approved for insomnia. Although lacking an FDA indication for insomnia, commonly prescribed agents are benzodiazepines, sedating antidepressants, sedating antipsychotics, and anticonvulsants (Buysse, 2013). Shared decision-making is ideally used for insomnia pharmacotherapy as evidence is insufficient to support use of medications, both FDA-approved and off label, for chronic insomnia.

Preconceptional Counseling

Value lies in counseling women before conception so that each pregnancy is planned with the goal to achieve the best maternal and fetal outcomes. With this in mind, topics found in Table 1-17 are ideally addressed.

TABLE 1-17. Preconceptional Counseling Topics

Topic	Recommendations
Abnormal weight	Calculate BMI yearly. *BMI ≥25 kg/m²:* Counsel on diet. Test for DM and metabolic syndrome if indicated *BMI ≤18.5 kg/m²:* Assess for eating disorder
Exercise	Uncomplicated pregnancy, engage in exercise before, during, and after
Substance abuse	Discuss perinatal effects of opioids, cocaine, methamphetamine, alcohol, smoking. Offer cessation options
Heart disease	Optimize function. Discuss warfarin, ACE inhibitor, and ARB teratogenicity, and if possible, switch agents prior to conception. Offer genetic counseling to women with congenital cardiac anomalies.
Hypertension	*Long-standing HTN*: assess ventricular hypertrophy, retinopathy, and renal disease. Discuss ACE inhibitor and ARB teratogenicity, and switch agents prior to conception
Asthma	Optimize function. Provide appropriate influenza and pneumococcal vaccines
Thrombophilia	Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If found, screen those contemplating pregnancy. Offer genetic counseling to those with known thrombophilia. Discuss warfarin teratogenicity, and switch agent, if possible, prior to conception
Renal disease	Optimize HTN. Discuss ACE inhibitor and ARB teratogenicity, and switch agents prior to conception
GI disease	*Inflammatory bowel disease:* Counsel on subfertility and risks of adverse pregnancy outcomes. Discuss MTX and mycophenolate mofetil, and switch agents, if possible, prior to conception

(Continued)

TABLE 1-17. Preconceptional Counseling Topics *(Continued)*

Topic	Recommendations
Liver disease	*Hepatitis B*: Vaccinate all high-risk women prior to conception (Table 1-1). Counsel chronic carriers on transmission prevention to partners and fetus *Hepatitis C*: Screen high-risk women (Table 1-1). Counsel affected women on risks of perinatal transmission. Refer for antiviral treatment, discuss risks of treatment during pregnancy
Blood disorders	*Iron-deficiency anemia:* Offer iron supplementation *Sickle-cell disease:* Screen all black women. Test partner as indicated *Thalassemias:* Screen all women *von Willebrand disease:* Counsel regarding postpartum hemorrhage risk
Diabetes	Optimize glucose control, especially periconceptionally due to known teratogenicity. Evaluate for retinopathy, nephropathy, HTN
Thyroid disease	Screen those with thyroid disease symptoms. Ensure iodine-sufficient diet. Treat overt hyper- or hypothyroidism prior to conception
CT disease	*RA and other inflammatory arthritides*: Counsel on flare risk after pregnancy. Discuss MTX and leflunomide teratogenicity, and switch agents prior to conception *SLE*: Optimize disease. Discuss mycophenolate mofetil and cyclophosphamide teratogenicity, and switch agents, if possible, prior to conception
Neurologic disorder	*Seizure disorder:* Optimize control using monotherapy, if possible
Psychiatric disorder	*Depression:* Screen for symptoms. If affected, counsel on risks of treatment and of untreated illness and high risk of peripartum exacerbation
Skin disease	Discuss isotretinoin and etretinate teratogenicity, and switch agents prior to conception
Cancer	*Current:* Counsel on fertility preservation options prior to cancer therapy and on decreased fertility following certain agents. Offer genetic counseling to those with mutation-linked cancers. Evaluate cardiac function in those given cardiotoxic agents. Discuss SERM teratogenicity, and switch agents prior to conception. Discuss possible teratogenic effects of chemotherapy if continued during pregnancy *Prior:* Update mammography for those given childhood chest radiotherapy. Discuss pregnancy risks of childhood abdominopelvic radiation (Chap. 28)
Infectious diseases	*Influenza:* Vaccinate all women prior to flu season *Malaria:* Avoid travel to endemic areas; chemoprophylaxis during conception *Rubella* or *Varicella:* Assess immunity, vaccinate as needed, and offer effective BCM during next 3 mos. *Tuberculosis:* Screen high-risk women and treat *Tetanus:* Update vaccination, as needed *Zika:* Abstain or use condoms after possible exposure for males (3 mos.) or females (2 mos.)
STDs	*Gonorrhea, syphilis, chlamydial infection:* Screen per Table 1-1 and treat as indicated *HIV:* For infection, treat prior to conception to decrease perinatal transmission. For discordant couple prevention, discuss PrEP if male partner viral load is not suppressed or is unknown (Chap. 3). *HPV:* Screen per guidelines (Chap. 29). Vaccinate as indicated *HSV:* Provide serological screening to asymptomatic women with affected partners. Counsel affected women on perinatal transmission risks and prophylaxis during the third trimester and labor

ACE = angiotensin-converting enzyme; ARB = angiotensin-receptor blocker; BMI = body mass index; CT = connective tissue; DM = diabetes mellitus; GI = gastrointestinal; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus; HTN = hypertension; MTX = methotrexate; PrEP = preexposure prophylaxis; RA = rheumatoid arthritis; SERM = selective estrogen-receptor modulator; SLE = systemic lupus erythematosus; STD = sexually transmitted disease.

Compiled from American College of Obstetricians and Gynecologist, 2017c,e, 2019; Centers for Disease Control and Prevention, 2017b, 2018b; Jack, 2008; Kim, 2018.

VIOLENCE AGAINST WOMEN

Sexual Violence

Sexual violence is a broad term that includes rape, unwanted genital touching, intimidation to acquiesce to sex, and forced viewing of or involvement in pornography (Basile, 2014). *Rape* is a legal term and in the United States refers to penetration or attempted penetration of a body orifice without consent and with force or the threat of force or incapacity (Federal Bureau of Investigation, 2013). A few states mandate clinicians to report rape of a competent adult to a law enforcement agency, and one list is provided by the National District Attorney Association (2016). In other states, law enforcement is involved at the patient's request. For the elderly and children, reporting is mandatory.

Large population-based surveys indicate a lifetime prevalence for sexual violence of 19 percent among women (Smith, 2017). Certain populations are at greater risk and include the disabled; lesbian, bisexual, or transgender individuals; college students; and persons younger than 24 years (Basile, 2016; Fedina, 2018; Taylor, 2016; Walters, 2013).

Examination and Documentation

Initial evaluation of a sexual violence victim concentrates on identifying serious injuries that may be genital or often nongenital (Riggs, 2000; Zilkens, 2017a). Once life-threatening injuries are excluded, a systematic, thorough, and compassionate approach to obtaining a history and collecting evidence is essential for appropriate treatment of the victim and for future prosecution of her assailant (American College of Obstetricians and Gynecologists, 2016a).

Valid evidence may be collected from 3 to 7 days after sexual assault, and timing varies by jurisdiction. Immediate examination enhances the opportunity to obtain valuable physical evidence. Consent is obtained prior to examination and evidence collection and is essential for entry of evidence in a court. Most states have standardized kits for collection, and completed kits are stored in a locked site to ensure that legal evidence procedures are maintained. Evidence collection does not commit a victim to pressing criminal charges. A patient is also counseled that she may terminate an examination if it is too emotionally or physically painful.

Evidence gathering follows the steps outlined in Table 1-18 (Department of Justice, 2013). In approximately 25 percent of female rape victims, evidence of anogenital injury is detected (Larsen, 2015; Zilkens, 2017b). Frequent injury types include tears, ecchymosis, abrasions, redness, and swelling (TEARS) (Slaughter, 1997). Common sites include the posterior fourchette, inner labial minora, and hymen. Colposcopy is used if available, and this technique raises detection rates of more subtle injuries (Astrup, 2012; Lenahan, 1998).

Treatment

Pregnancy Prevention. Medication prophylaxis to prevent pregnancy following sexual assault can be provided to at-risk women with reproductive organs. Among reproductive-aged victims, the risk of rape-related pregnancy approximates 5 percent per rape (Holmes, 1996). Emergency contraception can be administered for up to 120 hours after rape but is most effective in the first 24 hours (Table 5-11).

A negative pregnancy test to exclude a preexisting pregnancy is confirmed before administering emergency contraception. This is especially true for ulipristal (Ella), a progesterone antagonist,

TABLE 1-18. Important Elements of Examination and Evidence Collection Following Sexual Assault

Physical Examination
Perform full body examination; record injuries on body diagram
Inspect vulva, inner thighs, anus, and buttock; add colposcopic inspection if available; record injuries on anogenital diagram
Inspect vagina and cervix; add colposcopic inspection if available
Evidence Collection
Collect clothing and associated debris as a patient disrobes onto cloth sheet
Comb head hair; trim any matted hair that contains secretions. Cut head hairs from patient for comparison[a]
Comb pubic hair; trim any matted hair that contains secretions. Cut pubic hair from patient for comparison[a]
Scrape debris from beneath fingernails if the victim scratched assailant's skin or clothing
Collect swabs from vagina, mouth, and anus if penetrated during assault
Wipe sites of possible secretion exposure with saline moistened swab; save and label swab. Common examples include inner labia minora, perineum, breasts, or neck
Smear each swab onto individual microscope slide; save and label slide[a]
Laboratory Testing
Obtain toxicology testing if examination suggests or if patient states drugging
Collect patient's blood or saliva to serve as DNA reference
Obtain swabs and blood for STD testing and prophylaxis as detailed in Table 1-19.

[a]Collection practices varies by jurisdiction.
STD = sexually transmitted disease.
From Department of Justice, 2013.

TABLE 1-19. Pregnancy and Sexually Transmitted Disease Prophylaxis Following Sexual Assault

Testing

Pregnancy test (urine or serum); repeat at 4–6 wks
Serum testing for hepatitis B surface antigen, surface antibody, and core antibody
Serum testing for HIV and syphilis; repeat at 4–6 wks and 3 mos.
NAAT for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* from each penetrated site
NAAT for *Trichomonas vaginalis* from vagina
Microscopic evaluation of saline wet mount of vaginal discharge
If HIV PEP[a] is planned, add HCV antibody. Draw serum LFTs and serum creatinine level[b] and repeat both at 4–6 wks

Treatment

Levonorgestrel, ulipristal, or Yuzpe method for candidates: all dosages in Table 5-11
Ceftriaxone 250 mg intramuscularly, single dose[c]
Azithromycin 1 g orally, single dose[c]
Metronidazole 2 g orally, single dose[c]
Hepatitis B vaccination if not previously vaccinated (Table 1-1)
HPV vaccination if not previously vaccinated (Table 1-1)
If exposure ≤72 hrs ago, HIV PEP offered to suitable candidates (see text). Regimen given daily for 28 days:
Tenofovir disoproxil fumarate/emtricitabine (Truvada[d]) once daily ***plus*** raltegravir 400 mg (Isentress) twice daily

[a]Questions regarding PEP can be directed to the Clinician Consultation Center at 1-888-448-4911.
[b]With renal dysfunction and creatinine clearance <60 mL/min, tenofovir disoproxil fumarate/emtricitabine is not recommended, and consultation for other regimens is suggested.
[c]Antibiotic alternatives for exposure to *N gonorrhoeae*, *C trachomatis*, and *T vaginalis* are found in Chapter 3.
[d]Caution in those with chronic hepatitis B.
CBC = complete blood count; HCV = hepatitis C virus; HIV = human immunodeficiency virus; HPV = human papillomavirus; LFTs = liver function tests; NAAT = nucleic acid amplification test; PEP = postexposure prophylaxis.
Compiled from Centers for Disease Control and Prevention, 2015, 2016, 2018a; Seña, 2015.

because of fetal loss risks if used in the first trimester. With estrogen/progestin combinations, nausea and vomiting is a potential side effect, and an antiemetic can be prescribed 30 minutes prior to hormone administration (Table 42-7).

Patients are informed that their next menses may be delayed following this prophylaxis. Although current regimens are 74 to 89 percent effective, pregnancy testing is repeated at the follow-up visit at 4 to 6 weeks (Task Force on Postovulatory Methods of Fertility Regulation, 1998; Trussell, 1996; Yuzpe, 1982).

Sexually Transmitted Disease Prevention. The risk of acquiring an STD after rape has been estimated but varies by circumstances. The risk for trichomoniasis approximates 12 percent; gonorrhea, 4 percent to 12 percent; chlamydial infection, 2 to 14 percent; and syphilis, 5 percent (Jenny, 1990; Schwarcz, 1990). General recommendations for STD screening and for prophylaxis are listed in Table 1-19.

Of these, postexposure prophylaxis (PEP) for human immunodeficiency virus (HIV) is recommended in selected cases following sexual assault. These include rape by an assailant known to be HIV infected or by a person of unknown HIV status if exposure represents a substantial risk for acquisition (Seña, 2015). With known HIV infection, the estimated acquisition risk is 1 per 10,000 receptive penile-vaginal exposures and 138 per 10,000 receptive penile-anal exposures (Patel, 2014). HIV transmission associated with receptive oral intercourse is rare.

For potential HIV PEP candidates, the risks and side effects of the medications and need for close monitoring are discussed. Nausea is a common side effect. Thus, a prescription for an antiemetic such as promethazine, to be used as needed, is commonly provided. Importantly, if an initial HIV test result in the victim is positive, PEP is stopped and replaced with appropriate long-term antiretroviral therapy.

Because of the emotional intensity of the experience, a woman may not recall all the information provided, and thus written instructions are helpful. Survivors are referred to local rape crisis centers and encouraged to visit within 1 to 2 days. Sexual assault victims receive subsequent medical reevaluation 1 to 2 weeks later. After 4 to 6 weeks, if initial test results were negative for pregnancy, HIV, or syphilis, these are repeated (see Table 1-19). These later tests capture conditions that may have been undetectable during initial screening. HIV is again screened for at 3 months (Centers for Disease Control and Prevention, 2016). Additional hepatitis B and HPV vaccines are provided as dictated by vaccination schedule.

Psychological Response to Sexual Assault. Survivors of sexual assault may display an array of reactions that frequently include anxiety, agitation, crying, or a quiet, removed affect. Burgess and Holmstrom (1974) first characterized the "rape trauma syndrome" and its two response phases. The first acute disorganization phase lasts several weeks and is followed by a reorganization phase, lasting several weeks to years. Acutely,

shock and disbelief, fear, shame, self-blame, humiliation, anger, isolation, grief, somatic manifestations, and loss of control are common. During the reorganization phase, feelings of vulnerability, despair, guilt, and shame may continue. Longitudinal data indicate that sexual assault survivors are at increased lifetime risk for posttraumatic stress disorder (PTSD), mood disorders, somatic symptoms, and suicide contemplation or attempt (Linden, 2011; Smith, 2017). Health care providers ideally enlist the input of social workers or rape crisis counselors to help evaluate the patient's immediate and future emotional and safety needs.

Child Sexual Abuse

Definitions of sexual abuse in the child mirror those in the adult (Basile, 2014; Federal Bureau of Investigation, 2013). From one large U.S. survey, the estimated overall prevalence of youth sexual violence for females is 8 percent (Merrick, 2018). Thus, indicators that should prompt evaluation include: (1) statements by the minor or family of abuse, (2) genital or anal injury without concordant history of unintentional trauma, (3) identification of semen or pregnancy, or (4) STD diagnosis beyond the incubation period of vertical (natal mother-to-child) transmission. Health care providers in the United States are mandated to report suspected child maltreatment to an appropriate agency, such as child protective services or a law enforcement agency (Child Welfare Information Gateway, 2016).

Determining whether anogenital findings in children are normal variants or indicative of assault can be difficult, and these have been categorized according to the likelihood of associated sexual abuse. An exhaustive list of normal and indeterminate signs has been compiled by Adams and associates (2018), and those considered diagnostic are listed in Table 1-20. A provider completing the examination should have formal training in the evaluation of suspected child sexual abuse. Importantly, acute injuries associated with child sexual abuse heal and resolve rapidly. Thus, examination is completed as soon as assault is suspected (Smith, 2018b). As signs may be subtle, a careful history and full examination are carried out with the aid of photodocumentation, preferably using a colposcope.

The prevalence of STDs in child victims of sexual abuse is low (Girardet, 2009a). Thus, the decision to obtain specimens from a child is individualized. Situations that typically prompt child testing include: (1) signs or complaints of genital penetration or of an STD, (2) one STD already diagnosed, (3) suspected assailant with a high risk for STDs, (4) another household member with an STD, (5) abuse by a stranger, or (6) community with a high STD rate (Centers for Disease Control and Prevention, 2015).

Recommended testing includes a nucleic acid amplification test (NAAT) for *Neisseria gonorrhoeae* and *C trachomatis* from urine or vagina. Culture and wet mount evaluation of a vaginal swab specimen are preferred for *Trichomonas vaginalis* infection (Adams, 2018). Decisions regarding serologic testing for *Treponema pallidum*, HIV, and hepatitis B virus are individualized.

Although STDs found beyond the neonatal period raise suspicious for sexual abuse, this has exceptions. Perinatal transmission of *N gonorrhoeae*, *C trachomatis,* HIV, *T pallidum*, and *T vaginalis* is possible. Outside this circumstance, these infections suggest sexual contact. In contrast, herpes simplex virus, human papillomavirus, and *Molluscum contagiosum* infections can be transmitted nonsexually (Adams, 2018). Most hepatitis B virus infections in children result from household exposure to those chronically infected with the virus.

Routine STD prophylaxis for children who have been sexually abused is generally not recommended due to lower rates of infection and a greater guarantee of scheduled follow-up for test results. However, if the clinical setting dictates or if test results are found to be positive for infection, antibiotics are provided. Rates of HIV transmission following sexual abuse are also very low in children (Girardet, 2009b). However, HIV PEP is well tolerated by children and can be offered based on

TABLE 1-20. Findings of Sexual Contact in Suspected Child Sexual Abuse

Acute genital laceration or extensive bruising[a]
Acute perianal laceration
Hymeneal petechiae or abrasions
Perianal or fourchette scarring[a]
Healed hymeneal cleft(s) below 3 or 9 o'clock locations that extends to hymeneal base.
Signs of female genital mutilation (see Table 1-21)
Bite marks
Torn oral frenulum
Positive testing for *Neisseria gonorrhoeae, Chlamydia trachomatis, HIV, Treponema pallidum*[b]
Pregnancy
Sperm identified in specimens taken directly from a child's body

[a]If other medical conditions such as Crohn disease, coagulopathy, accident, or labial adhesion not explanatory for findings.
[b]If perinatal transmission, transmission from blood products, and needle contamination have been excluded.
HIV = human immunodeficiency virus.
Compiled from Adams, 2007, 2018; Chiesa, 2017.

the clinical setting and within the first 72 hours. The CDC (2015) recommends consulting professionals who specialize in care of HIV-infected children.

Elder Abuse

This is an intentional act or failure to act by a trusted individual that causes or creates a risk of harm to an older adult. Elder abuse may include neglect or physical, psychologic, sexual, or financial abuse (Hall, 2016). Approximately 10 percent of the elderly are mistreated each year (Acierno, 2010). Identified risk factors are caregiver stress, patient cognitive impairment, need for assistance with daily life activities, conflicted family relationships, and poor social support (Hoover, 2014). Similar to other forms of violence, elderly victims can suffer subsequent depression, anxiety, PTSD, and poor self-reported health (Acierno, 2017; Wong, 2017).

Signs that can be associated with abuse are decubitus ulcers, poor hygiene, poor adherence to medication regimens, or signs of trauma, sexual assault, dehydration, or malnutrition. Psychologic clues include depression, anxiety, cowering, vague somatic complaints, and social withdrawal (Lachs, 2015). Physicians are mandated in most states to report suspicion of elder abuse, and each state's "mandatory reporting" requirements are posted by the Department of Justice (2016). Sexual and physical assault will involve local law enforcement. Reports of other abuse forms are typically filed with the Adult Protective Services agency of the given state (National Adult Protective Services, 2018).

Intimate Partner Violence

Intimate-partner violence (IPV) refers to harm inflicted by one intimate partner on the other, with the intent of causing pain or controlling the other's behavior. *Domestic violence, violence against women,* and *gender-based violence* are older synonyms. *Honor-based violence (HBV)* is a subcategory in which male family members act against female members to maintain family honor in the community.

IPV takes various forms and includes sexual violence, physical violence, stalking, and psychological aggression or coercion (Breiding, 2015). Most victims have been assaulted more than once and often over the course of years. In the United States, nearly one third of women experienced physical violence by an intimate partner in their lifetime, one quarter suffered severe violence, and 16 percent have described contact sexual violence (Smith, 2017). Rates of IPV are higher in adolescents and those who witnessed violence as a child (Jung, 2018; Kann, 2018; Smith, 2017). Pregnant women may also be victims, and homicide is the leading cause of death during pregnancy (Palladino, 2011; Shadigian, 2005).

Diagnosis

Numerous health complications follow IPV. Short-term sequelae include acute injuries, pregnancy, and STD acquisition (Smith, 2017). Gravely, in the United States in 2015, 45 percent of female homicides were IPV-related (Jack, 2018). Long term, mental health consequences such as PTSD, anxiety, depression, suicide attempt, and substance abuse are prominent (Iverson, 2013). Chronic somatic complaints often focus on gastrointestinal dysfunction, genitourinary pain, and other chronic pain (Campbell, 2002; Centers for Disease Control and Prevention, 2008). Effects on sexual function are discussed in Chapter 14.

Women who have been assaulted are far more likely to seek help from their medical provider. Although some clinicians may feel awkward asking patients, researchers agree that the single most important thing a physician can do for a battered woman is to ask about violence (American College of Obstetricians and Gynecologists, 2012). Additionally, symptoms or behaviors that may be associated with victimization are investigated. Numerous formal assessment tools are available from the CDC (Basile, 2007).

Management

If a patient discloses IPV, a clinician should validate and normalize a patient's perspective. Patients are counseled that many women have assault experiences, that most are afraid to confide these, that memories of the experience can be painful, and that a fear of future assaults is a reasonable fear. Following a patient's disclosure, a provider expresses concern for the woman's health and safety and conveys a willingness to discuss relationship issues at any time. Moreover, information describing community resources is offered. The National Domestic Violence Hotline (1-800-799-SAFE (7233)) is a nonprofit telephone referral service with access to more than 5000 shelters nationally.

Battery is a crime, yet few states specifically require mandatory reporting of IPV. Accordingly, each clinician should know their state laws, and one list has been compiled by Durborow and associates (2013). In addition, providers ideally thoroughly document physical findings of violence. Such data may be required if criminal charges are pursued.

Female Genital Mutilation

This practice refers to medically unnecessary vulvar modification. In the United States, it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years or to send or attempt to send her outside the country so it can be performed. That said, female genital mutilation (FGM) is practiced in countries within Africa, the Middle East, and Asia. As many as 200 million women worldwide have undergone one of these procedures, and approximately 513,000 girls in the United States were at risk for this practice in 2012 (Goldberg, 2016; UNICEF, 2016). Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been assaulted or mutilated (American College of Obstetricians and Gynecologists, 2014). The World Health Organization (2008) classifies genital mutilations into four types (Table 1-21).

Long-term complications from surgery and its associated scarring include infertility, chronic vulvar pain, diminished sexual quality of life, propensity for urogenital infection, difficulty passing menstrual blood, and formation of a vulvar neuroma, epidermoid cyst, or keloid (Almroth, 2005; Andersson, 2012; World Health Organization, 2018). Moreover, cervical cancer screening may not be possible.

In general, women with significant symptoms following type III procedures are candidates for *defibulation*. This procedure sharply divides scar tissue at the midline to reopen the vulva

TABLE 1-21. World Health Organization Classification of Female Genital Mutilation

Type Ia	Prepuce (clitoral hood) removal
Ib	Prepuce, clitoris removal
Type IIa	Labia minora removal
IIb	Labia minora, clitoris removal
IIc	Labia majora and minora, clitoris removal
Type IIIa	Removal and surgical apposition of labia minora ± clitoris removal
IIIb	Removal and surgical apposition of labia majora ± clitoris removal
Type IV	Pricking, piercing, incising, scraping, cautery, or other genital injury

(Chap. 43). Following surgery, sexual functioning is typically improved (Krause, 2011; Nour, 2006). Also, gravidas with type III FGM may benefit from lower rates of both cesarean delivery and higher-order perineal laceration following defibulation (Berg, 2018).

In contrast, results of clitoral reconstruction are mixed, and outcome data are limited. Surgery provides a visible clitoris in approximately 75 percent of cases. Average improvement scores for desire, dyspareunia, pleasure, and sexual frequency range from 40 to 60 percent. However, worsening of these last four parameters is seen in 2 to 20 percent of women (Berg, 2018). During presurgical evaluation for clitoral reconstruction, patients may be best served by a team that includes gynecologic, psychological, and sexual counseling to discuss treatment options (De Schrijver, 2016).

Several technical advances in recent decades currently allow superb imaging of female pelvic structures. As a result, use of sonography in gynecology now equals that in obstetrics. Enhancements to traditional sonography continue to fill important clinical gaps. For example, technical refinements now allow three-dimensional (3-D) imaging to rival the roles of computed tomography (CT) and magnetic resonance (MR) imaging for many conditions. In addition, application of MR imaging now includes MR-guided high-intensity focused-ultrasound therapy, used for uterine leiomyomas.

SONOGRAPHY

Physics

In sonography, the picture displayed on a screen is produced by sound waves reflected back from an imaged structure. To begin, alternating current is applied to a transducer containing piezoelectric crystals, which convert electric energy to high-frequency sound waves. A water-soluble gel applied to the skin acts as a coupling agent. Sound waves then pass through tissue layers, encounter an interface between tissues of different densities, and are reflected back to the transducer. Converted back into electric energy, they are displayed on a screen.

Dense material, such as bone, or a synthetic material, such as an intrauterine device (IUD), produces high-velocity reflected waves, also termed *echoes*, which are displayed on a screen as white. These are described as *echogenic*. Conversely, fluid is *anechoic,* generates few reflected waves, and appears black on a screen. Middle-density tissues variably reflect waves to create various shades of gray, and images are described as *hypoechoic* or *hyperechoic* relative to tissues immediately adjacent to them. Images are generated so quickly—50 to 100 frames per second—that the picture on the screen appears to move in real time.

Sound reflection is greatest when the difference between the acoustic impedance of two structures is large. This explains why cysts are so well demonstrated with sonography. Strong echoes are produced from the cyst walls, but no echoes arise from the cyst fluid. As more sound traverses the cyst, more echoes are received from the area behind the cyst, a feature known as *through transmission* or *acoustic enhancement* (Fig. 2-1). In contrast, with a dense structure, the sound passing through it is diminished, which creates a band of reduced echoes beyond it, known as *acoustic shadowing* (Fig. 2-2).

The frequency of emitted ultrasound waves is expressed in megahertz (MHz), which means million vibrations per second. The frequency is inversely related to its wavelength. Thus, transducers emitting pulses of high frequency generate waves of shorter length, which result in higher spatial resolution or sharpness between interfaces but achieve less penetration. Curved transducers provide a wider field of view but often generate lower-frequency waves than linear transducers. Higher-frequency probes (10 to 15 MHz) are used to image superficial structures, such as breast masses or lost etonogestrel implants in the upper arm. Lower frequencies are required to image deeper structures. As such, transabdominal transducers are typically in the

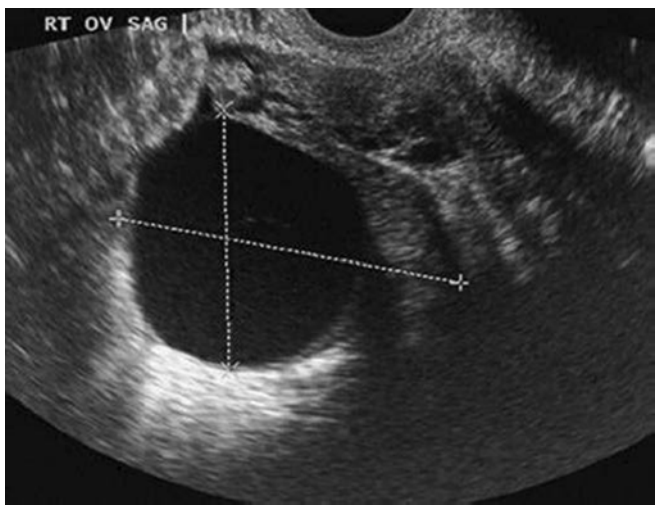

FIGURE 2-1 Transvaginal sonogram of a premenopausal ovary containing a follicular cyst. The cyst fluid appears black or anechoic. Note the white or hyperechoic area under the cyst, a sonographic feature called *posterior acoustic enhancement* or *through transmission*.

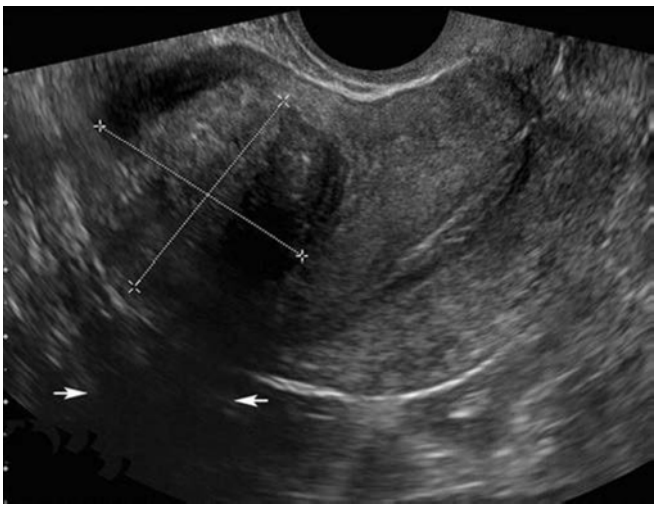

FIGURE 2-2 Transvaginal sonogram shows a leiomyoma marked by calipers and demonstrates *posterior acoustic shadowing* (*arrows*).

3 to 5 MHz range, whereas transvaginal transducers are generally 5 to 10 MHz.

Examination Techniques

Guidelines for sonographic examination of the female pelvis have been established by The American Institute of Ultrasound in Medicine (2014). These serve as quality assurance standards for patient care and provide assistance to practitioners performing sonography. Guidelines describe equipment and documentation and may be accessed at: http://www.aium.org/resources/guidelines/femalePelvis.pdf.

All probes are cleaned after each examination, and vaginal probes are covered by a protective sheath prior to insertion. A female staff member should always chaperone transvaginal sonography. Guidelines describe the examination steps for each organ and anatomic region in the female pelvis. For the uterus, uterine size, shape, orientation, and description of the endometrium, myometrium, and cervix are documented. The examination and its interpretation are permanently recorded, appropriately labeled, and placed in the medical record. A copy is also kept by the facility performing the study.

Grayscale Imaging

Various examination techniques can be used for sonographic study of the female pelvis. Of these, transabdominal evaluation, using a curved-array 3- to 5-MHz transducer, is the first component of general gynecologic examinations. It provides global identification of all pelvic organs and their spatial relationships. In a nonpregnant patient, a full bladder is preferred for adequate viewing, as it pushes the uterus upward from behind the pubic symphysis and displaces small bowel from the field of view. Moreover, the bladder acts as an *acoustic window*, to improve ultrasound wave transmission. In patients with large lesions or masses located superior to the bladder dome, transabdominal sonography provides a panoramic view for greater disease evaluation. Still, endometrial cavity assessment is limited with a transabdominal approach and often requires the transvaginal technique.

Transvaginal sonography (TVS) uses higher-frequency (5- to 10-MHz) transducers and is the second component of general gynecologic examinations. Because of its greater sensitivity and spatial image resolution, TVS is ideal for interrogating pelvic anatomy within the confines of the true pelvis. With larger masses, imaging may be incomplete and is complemented by transabdominal sonography.

For TVS, the probe is positioned in the vaginal fornices to place the transducer close to the region of interest and thereby lessen beam attenuation by superficial soft tissues. In contrast to transabdominal imaging, the bladder is emptied prior to a transvaginal study. TVS has few limitations. The only two absolute contraindications are imperforate hymen and patient refusal. A relative contraindication is a patient with a virginal or strictured introitus. These women, however, can usually undergo comfortable examination with proper counseling.

Transrectal and *transperineal techniques* employ transrectal probes and conventional transducers placed over the perineal region, respectively, for image acquisition. Much less commonly used, they are selected for indications such as pelvic floor imaging (p. 38).

Harmonic Imaging

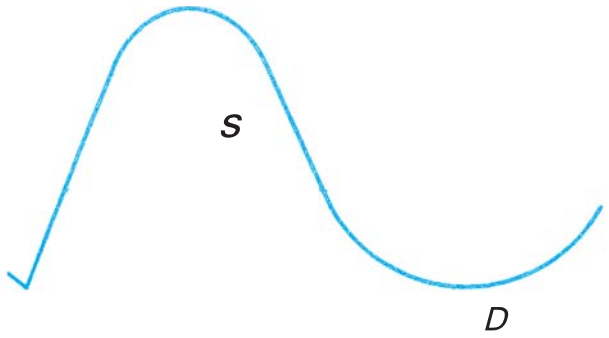
This recent modification of sonography improves image quality by using several frequencies at once from the transmitted ultrasound beam instead of just a single frequency. Newer probes and postprocessing features enhance image resolution, particularly at surface interfaces. Visual artifacts that arise from superficial structures such as adipose are reduced. As such, tissue harmonic imaging is routinely used in our institution's ultrasound examinations.

Doppler Technology

This ultrasound technique can be performed with either transabdominal or transvaginal sonography to determine blood flow through pelvic organs, based on the red blood cell (RBC) velocity within vessels, especially arteries. *Color Doppler* captures and characterizes the spectral waveform of flow through certain vessels seen during real-time imaging. Ratios are often used to compare these different waveform components. The simplest is the systolic-diastolic ratio (S/D ratio), which compares the maximal (or peak) systolic flow and end-diastolic flow to evaluate downstream impedance to flow (Fig. 2-3). Of arterial Doppler spectral waveform parameters, the *resistance index* and *pulsatility index* also are commonly calculated. These quantitative indices estimate the impedance to RBC velocity within the artery by expressing the differences between the peak systolic and end-diastolic velocities.

A second application is *color Doppler mapping*, in which the color-coded pulsed-Doppler velocity information is superimposed on the real-time grayscale image. The color is scaled such that the color brightness is proportional to the flow velocity. Additionally, color Doppler also provides information regarding blood flow direction, and color is assigned to this. Flow approaching the transducer is customarily displayed in red, and flow away from it is shown in blue.

Color Doppler is not applied during every general gynecologic examination. One frequent indication is adnexal mass



$$\frac{S}{D} = S/D \text{ Ratio}$$

$$\frac{S-D}{S} = \text{Resistance index}$$

$$\frac{S-D}{\text{Mean}} = \text{Pulsatility index}$$

FIGURE 2-3 Doppler systolic–diastolic waveform indices of blood flow velocity. *S* represents the peak systolic flow or velocity, and *D* indicates the end-diastolic flow or velocity. The mean, which is the time-average mean velocity, is calculated from computer-digitized waveforms. (Reproduced with permission from Dashe, 2018.)

interrogation. Neovascularity within cancer is composed of abnormal vessels that lack smooth muscle and contain multiple arteriovenous shunts. Consequently, low-impedance flow is expected with such masses (Fig. 2-4) (Timmerman, 2016; Weiner, 1992). Other indications include evaluation of ovarian masses for torsion, detection of extrauterine vascularity associated with ectopic pregnancy, and assessment of uterine perfusion in patients with leiomyomas and endometrial disorders (Navve, 2013; Wang, 2016a). Because of safety concerns regarding the higher intensities generated by color and spectral Doppler, use of Doppler imaging in the first trimester is discouraged, unless clear indications are present.

Power Doppler imaging also maps RBC motion. It detects the energy of Doppler signals generated from moving RBCs using

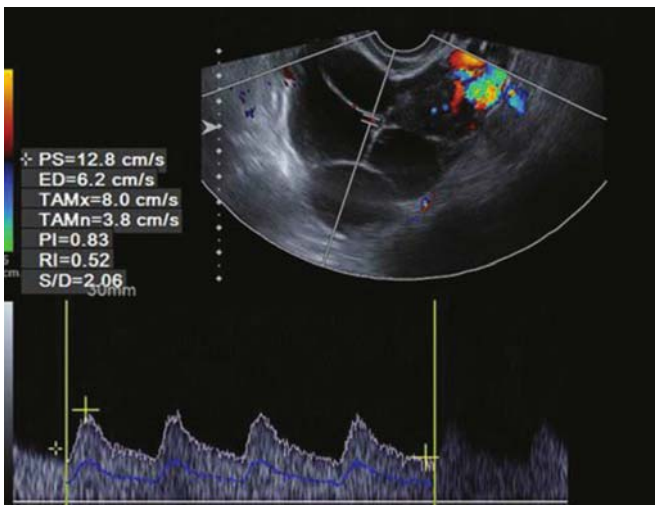


FIGURE 2-4 Complex ovarian mass with irregular cystic areas demonstrating low-impedance (pulsatility index = 0.83) flow in a septation.

FIGURE 2-5 Power Doppler evaluation of a gestational sac in the lower uterine segment. Circular flow is depicted, consistent with the peritrophoblastic flow of an implanted pregnancy.

signal-to-noise characteristics of the vessels compared with surrounding tissues. This modality gives no information regarding blood flow direction, and thus data are displayed as a single color, usually yellow or orange. However, power Doppler is more sensitive to low-flow velocities, such as in veins and small arteries. Although employed less often than color Doppler mapping, power Doppler can gather additional information regarding endometrial and ovarian abnormalities (Fig. 2-5).

Saline-Infusion Sonography

Also called *sonohysterography*, saline-infusion sonography (SIS) displays detailed endometrial cavity anatomy by distending the cavity with sterile saline (American College of Obstetricians and Gynecologists, 2016). It is commonly selected after an endometrial mass is identified or suspected during general TVS. SIS can also assist in some infertility investigations and aid viewing of the central endometrial echo if it is poorly imaged because of uterine position or pathology.

After voiding, a woman first undergoes a comprehensive TVS evaluation. A vaginal speculum is then inserted, and the vagina and cervix are swabbed with an antiseptic solution. A catheter primed with sterile saline is advanced into the cervical canal and past the internal os. We do not routinely use a tenaculum for this. Contact with the uterine fundus is ideally avoided when advancing the catheter to avert pain or vasovagal response. It can also shear away endometrium, causing false-positive results. Once in the lower uterine segment, the catheter balloon is inflated. The speculum is carefully removed, the transvaginal probe is reinserted, and sterile saline is injected through the catheter at a rate based on the patient's tolerance. Usually not more than 5 to 40 mL is required to distend the endometrial cavity, depending on the patient's hormonal status and intracavitary pathology (Fig. 2-6). During this time, the cavity is observed with TVS. The sonographer scans in the longitudinal plane, imaging from one cornu to the other, and in the transverse plane, from the top of the fundus to the cervix. Endometrial surface irregularities are well delineated by the anechoic contrast of saline. At the procedure's conclusion,

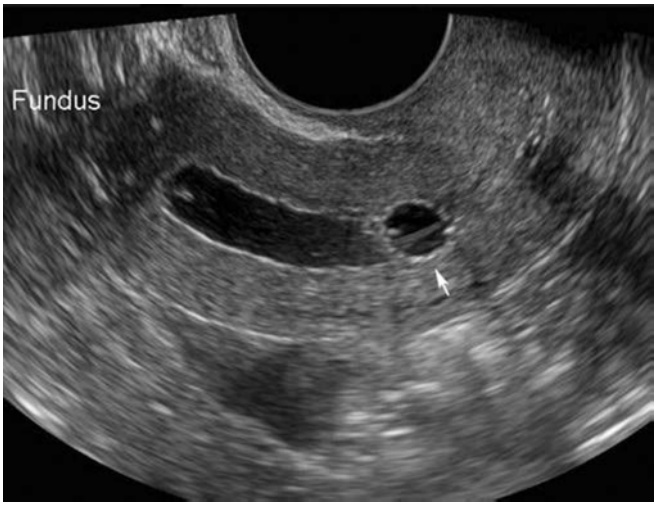

FIGURE 2-6 Saline-infusion sonography of a normal endometrial cavity. The infusion catheter balloon (*arrow*) is seen in the uterine isthmus.

the catheter is withdrawn under sonographic visualization. The uterine isthmus, endocervical canal, and upper vagina and vaginal fornices also may be evaluated, and this technique is referred to as *sonovaginography*. On average, the entire procedure lasts 5 to 10 minutes.

Many different catheter systems are available, including rigid systems and flexible catheters with and without attached balloons. We use a 7F SIS balloon catheter set, which tamponades the internal cervical os. This blockade prevents backflow of the distending medium and provides stable filling and adequate distention. We have found it easy to place and well tolerated (Fig. 2-7). Several distending solutions have been described, including saline, lactated Ringer solution, and 1.5-percent glycine. Sterile saline is inexpensive and provides optimal imaging. Alternatively, gel and foam substances have been developed to avoid backflow problems. However, these alternative products have not been extensively investigated and are not used widely in clinical practice.

In the premenopausal woman, SIS is best performed within the first 10 days of the menstrual cycle, and optimally on cycle days 4, 5, or 6 when the lining is thinnest. This timing is recommended to avoid misinterpreting menstrual blood clots as intrauterine pathology or missing pathology obscured by thick endometrial growth. In addition, such timing usually precludes disturbing a potential pregnancy. For the postmenopausal woman, timing of the procedure is not cycle-dependent.

Complications of SIS are minimal, and the risk of infection is <1 percent (Bonnamy, 2002). The American College of Obstetricians and Gynecologists (2018) recommends prophylactic antibiotics for women with prior pelvic inflammatory disease (PID) or identified hydrosalpinges, in which cases doxycycline 100 mg orally twice daily is prescribed for 5 days. Although not evidence based, we also routinely give a single dose of doxycycline, 200 mg orally, following SIS in women with diabetes and to infertile patients because of the risk for significant tubal damage associated with pelvic infection. Pain is usually minimal. In our experience, women with prior tubal ligation have greater discomfort, likely because fluid is unable to efflux through the fallopian tubes. A nonsteroidal antiinflammatory drug (NSAID) given 30 minutes prior to the procedure will typically minimize discomfort.

Contraindications to SIS include hematometra, pregnancy, active pelvic infection, or obstruction such as with an atrophic or stenotic cervix or vagina. In postmenopausal women with cervical stenosis, we have found the following steps to be helpful. First, a 200-μg misoprostol tablet is taken orally the evening before and the morning of the procedure. During SIS, a paracervical block with 1-percent lidocaine without epinephrine is provided; a tenaculum is placed on the cervix for traction; and the cervix undergoes sonographically guided sequential cervical dilation with lacrimal duct dilators. To overcome severe cervical stenosis, Pisal and colleagues (2005) inserted a 20-gauge spinal needle directly into the uterine cavity under sonographic guidance to deliver the saline.

Hysterosalpingo-Contrast Sonography

In the past, a fallopian tube could be detected with sonography only when distended by fluid, such as with obstruction. Injection of echogenic contrast during real-time sonography,

FIGURE 2-7 **A.** Saline-infusion sonography catheter. **B.** Saline-infusion sonography technique.

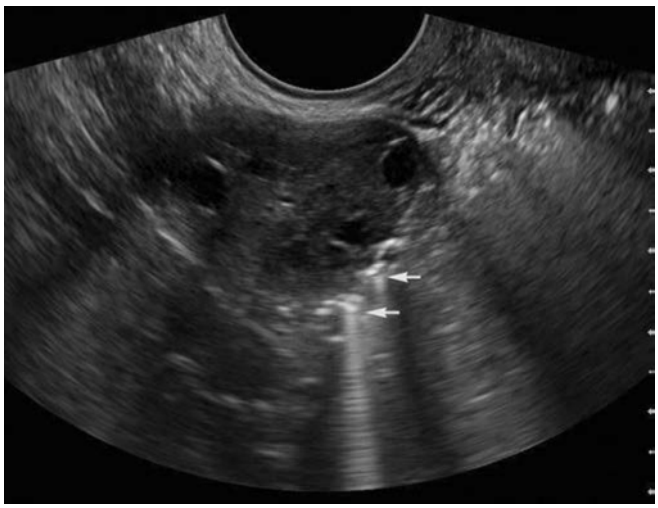

FIGURE 2-8 Transvaginal image of an ovary with echogenic bubbles adjacent to it (*arrows*) as seen during hysterosalpingo-contrast sonography (HyCoSy). The air in the saline contrast produces the bright echo and ring-down artifacts. Visualization of these echoes adjacent to the ovary represents contrast exiting the tube, consistent with tubal patency.

called *sonosalpingography*, *sonohysterosalpingography*, or *hysterosalpingo-contrast sonography (HyCoSy)*, is now an accurate first-line procedure to assess tubal patency (Lo Monte, 2015).

HyCoSy is done in a manner similar to SIS. Fluid egress from the uterine cavity is blocked by a balloon catheter within the cervical canal. Using transvaginal sonography, the fallopian tubes are identified at the point where they join the uterine cornua. A hyperechoic sonographic contrast medium (Echovist, Albunex, or Infoson) is injected through the catheter to fill the cavity and then the fallopian tubes (Fig. 2-8). Air coupled with sterile saline solution is another contrast option. With either medium choice, patent tubes appear hyperechoic as they fill with contrast. Color or pulsed Doppler techniques raise the diagnostic accuracy of HyCoSy by showing flow velocity within the tubes (Kupesic, 2007). We use the FemVue Sono Tubal Evaluation System, which simultaneously introduces air and sterile saline in a controlled fashion. The positive pressure flow of the echogenic mixture creates "scintillations" that are visually followed using real-time ultrasound. In patent tubes, flow proceeds from the uterotubal junction, through the length of the tube, and out the fimbriated end. Bubbles then surround the ovary or fill the posterior cul-de-sac. At present no large studies quantitate a risk for post-HyCoSy pelvic infection, and our periprocedural antibiotic prophylaxis mirrors that for SIS.

HyCoSy performed in conjunction with SIS provides a comprehensive "one-stop" outpatient assessment of tubal patency, adnexal architecture, and uterine cavity and myometrial anatomy. Comparable to hysterosalpingography (HSG) in detecting tubal pathology and anatomy, HyCoSy is well tolerated and avoids x-ray exposure or iodine-related allergic reaction (Lo Monte, 2015; Luciano, 2014).

However, HyCoSy does have limitations. First, similar to HSG, tubal spasm can provide false-positive occlusion results with HyCoSy. In addition, a patent tube does not always correlate with normal tubal function. Second, the entire fallopian tube often cannot be visualized due to normal tubal tortuosity. To that end, recent studies have evaluated the combination of 3-D sonography with HyCoSy for more accurate delineation of tubal anatomy (Alcázar, 2016; Exacoustos, 2017; Wang, 2016b).

Three-Dimensional Sonography

Technical Aspects. The ability to obtain certain views of pelvic organs in two dimensions is inherently limited. Transabdominally, the bony pelvis prevents scanning from the pelvic sidewall. Transvaginally, the views obtainable are restricted by the range of vaginal probe mobility. Sonography scanners now can collect 3-D data and represent it on a two-dimensional (2-D) screen. With 3-D imaging, any desired plane through a pelvic organ can be obtained, regardless of the sound beam orientation during acquisition. For example, the "face-on" or coronal plane through the uterus is routinely seen in 3-D imaging but is rarely viewed during 2-D scanning. This view of the uterus is essential for assessing the external contour, particularly of the fundus, for congenital uterine anomaly diagnosis.

With 3-D sonography, a volume, rather than a slice, of sonographic data is acquired and stored. The stored data can be reformatted and analyzed in numerous ways, and navigation through the saved volume can show countless planes. At any time, the volume can be retrieved, studied, reconstructed, and reinterpreted as needed. In addition, the level of energy with 3-D sonography is no higher than with 2-D, and manipulations of the obtained volumes are performed "off-line" to avoid additional ultrasound scanning time.

The three main components of 3-D sonography are volume acquisition, processing, and display. First, the preferred method to acquire volumes is automated and uses a dedicated 3-D probe that contains a mechanized drive. When these probes are activated, the transducer elements automatically sweep through the operator-selected region of interest, called a *volume box*, while the probe is held stationary.

After the appropriate volume is acquired, the user can begin to process the volume using the modes available in the ultrasound machine. The acquired volume can be displayed multiple ways. The most common is multiplanar reconstruction, in which three perpendicular planes, sagittal (the longitudinal plane that divides the body into right and left sections), axial (the transverse plane that divides the body into top and bottom sections), and coronal (the frontal plane that divides the body into front and back sections), are displayed simultaneously. Correlation between the three planes in the multiplanar display is accomplished by placing the planar center dot at the point of interest in one plane and observing the location of the corresponding center dots in the other two planes (Fig. 2-9A–C).

Abuhamad and associates (2006) have described a straightforward postprocessing technique that aids in the manipulation of 3-D volumes of the uterus, called the *Z technique*. The anatomic basis of the Z technique is such that, in aligning the midsagittal and midtransverse planes of the uterus parallel to the horizontal axis, the midcoronal plane of the uterus will easily and consistently be displayed. In addition, all or part of the saved volume can be processed into a rendered image that can

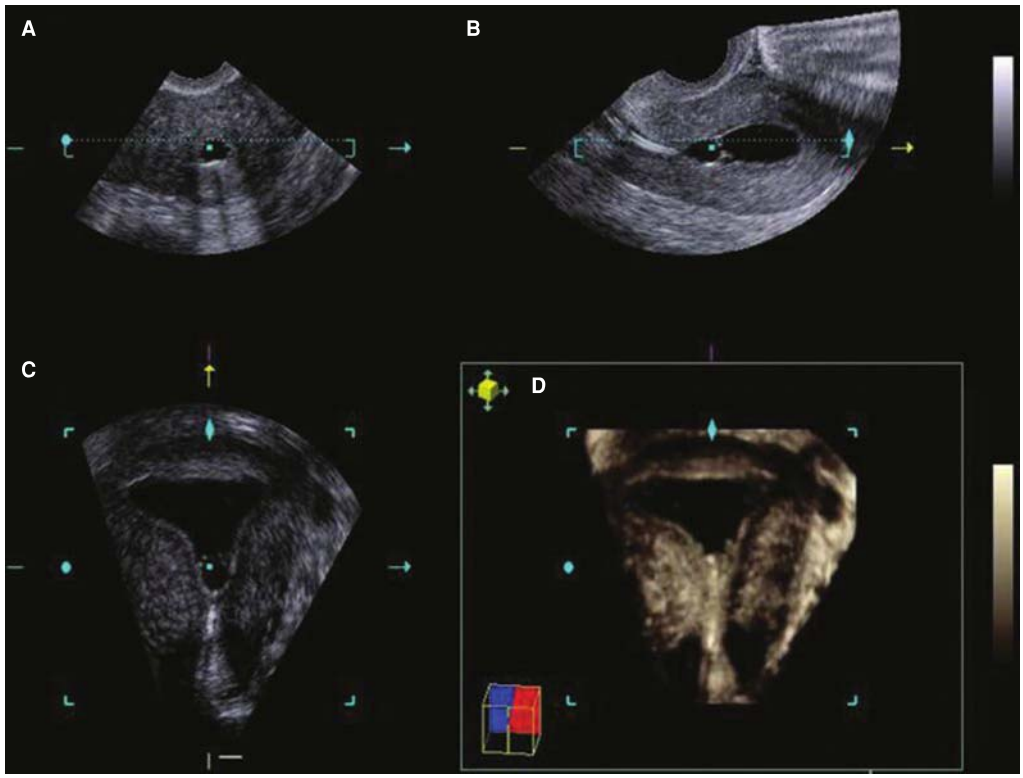

FIGURE 2-9 Multiplanar display of a 3-dimensional volume of a uterus and normal endometrial cavity during saline-infusion sonography. The views were obtained from a midsagittal reference plane using the Z technique. The planes are as follows: **A.** transverse, **B.** sagittal, **C.** coronal, **D.** rendered image.

be shown alone or in correlation with the multiplanar display. A rendered image is a "sum" of all the coronal planar images (see Fig. 2-9D). This is the display method that has been publicized in obstetrics, when showing the image of a fetal face in utero.

The inverse mode is a rendering technique of the entire volume in which all cystic areas within the volume become digitally opaque and all solid areas become transparent. This technique is useful when trying to see cystic areas that might be hidden in a volume, such as within an ovarian mass. Last, the volume can be displayed in parallel tomographic slices, similar to the displays used by CT and MR imaging.

3-D imaging is not without shortcomings. With 3-D sonography, the same type of acoustic artifacts that occur with 2-D imaging are encountered, such as acoustic shadowing and enhancement, refraction and reverberation, and motion artifacts from bowel peristalsis and vascular pulsation. Another potential pitfall in 3-D imaging of the pelvis involves spatial orientation within the saved volume data. Uterine flexion or version or left versus right may not be readily apparent on review of saved volumes. As such, during the preliminary real-time scanning, the operator must determine the orientation of the area of interest and notate it accordingly.

Another problem is related to the limited size of the volume box. Because of this, the entire uterus is often not acquired in a single volume. In some cases, it may be necessary to acquire two volumes, one for the cervix and a second for the uterine body. Likewise, a very large adnexal mass may not be imaged completely in any single volume of data obtained transvaginally. The size of the volume box provided by the abdominal probe is greater. Thus with 3-D sonography, a large mass may need to be imaged transabdominally instead of transvaginally.

Clinical Use. Because it can study organs in numerous scanning planes, 3-D imaging has become invaluable in gynecology to assess the uterine cavity, complex ovarian masses, ovarian fertility reserve, uterine anomalies, and interstitial pregnancies. It simultaneously provides anatomic and dynamic information from pelvic floor structures and also from mesh implants.

Of these, mapping leiomyoma location relative to the endometrial cavity and surrounding structures is an essential step in triaging patients for treatment (Chap, 9, p. 206). For such mapping, 3-D sonography, in particular 3-D SIS, has been used in place of convention SIS or MR imaging (Keizer, 2018; Mavrelos, 2011). In patients receiving gonadotropin-releasing hormone (GnRH) agonists or following uterine artery embolization (UAE), 3-D sonography can also monitor leiomyoma volume reductions. However, following UAE, MR imaging is more often used.

Abnormalities of the endometrium and adjacent myometrium, especially focal endometrial thickenings such as polyps and cancer, may be better defined with 3-D technology (Fig. 2-10) (Benacerraf, 2008). In a recent Cochrane database review, 3-D SIS offered uterine cavity and endometrial thickness visualization rates comparable to hysteroscopy (Nieuwenhuis, 2017). We now routinely implement 3-D imaging for evaluation of abnormal endometrium during our TVS studies and with all SIS procedures.

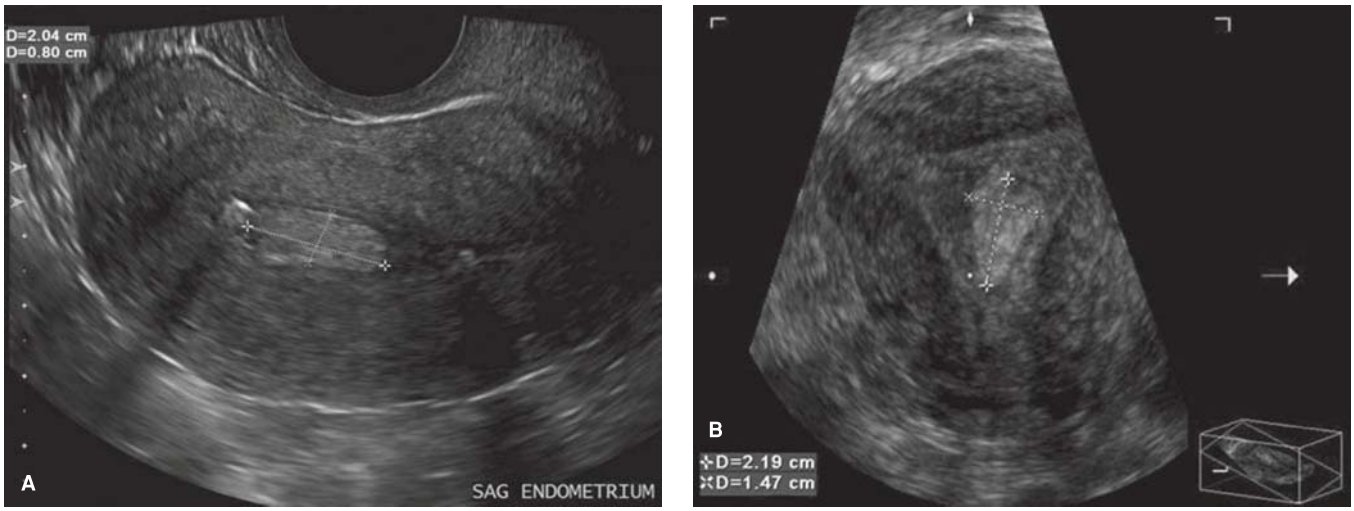

FIGURE 2-10 A. Transvaginal sonogram displays endometrial polyp measured by calipers. **B.** Three-dimensional image in the coronal plane of a polyp (*calipers*).

Although investigational, 3-D sonography with power Doppler angiography (3D-PDA) can help discriminate benign from malignant endometrial disease in women with postmenopausal bleeding and a thickened endometrium (Makled, 2013). Endometrial lesions in infertile women are another potential indication (Ni, 2019). 3D-PDA can assess endometrial volume, which may more accurately reflect true tissue volume than a 2-D endometrial thickness measurement. Another tool, 3-D power Doppler imaging enhanced by intravenous (IV) contrast, also is being studied to distinguish benign endometrial polyps from endometrial cancer (Lieng, 2008; Song, 2009).

IUD positioning within the endometrial cavity can be documented adequately in most cases with traditional 2-D TVS. That said, 3-D sonography offers improved visualization, especially with the levonorgestrel-containing IUDs (Moschos, 2011). The coronal plane images, which are not possible with 2-D imaging, provide views of the arms and shaft of the device and their relation to the endometrial cavity (Benacerraf, 2009). At our institution, patients undergoing gynecologic sonography with an IUD in situ, regardless of the study indication, have both a standard 2-D evaluation and a 3-D volume acquisition of the uterus. The coronal view of the endometrial cavity is reconstructed to establish IUD type, location, and positioning (Fig. 2-11). TVS also is an acceptable method to confirm proper Essure coil positioning (Fig. 2-12) (Carretti, 2019; Legendre, 2010).

For adnexal mass interrogation, most agree that 3-D sonography provides detailed internal anatomy (Alcázar, 2003). Moreover, 3D-PDA displays the internal architecture and also the neovascularization characteristic of malignant neoplasms. However, 3D-PDA does not significantly improved diagnostic accuracy compared with that of grayscale and 2-D power Doppler imaging (Jokubkiene, 2007; Ohel, 2010).

In reproductive medicine, 3-D imaging acquires more precise ovarian volumes and follicle counts than measurements

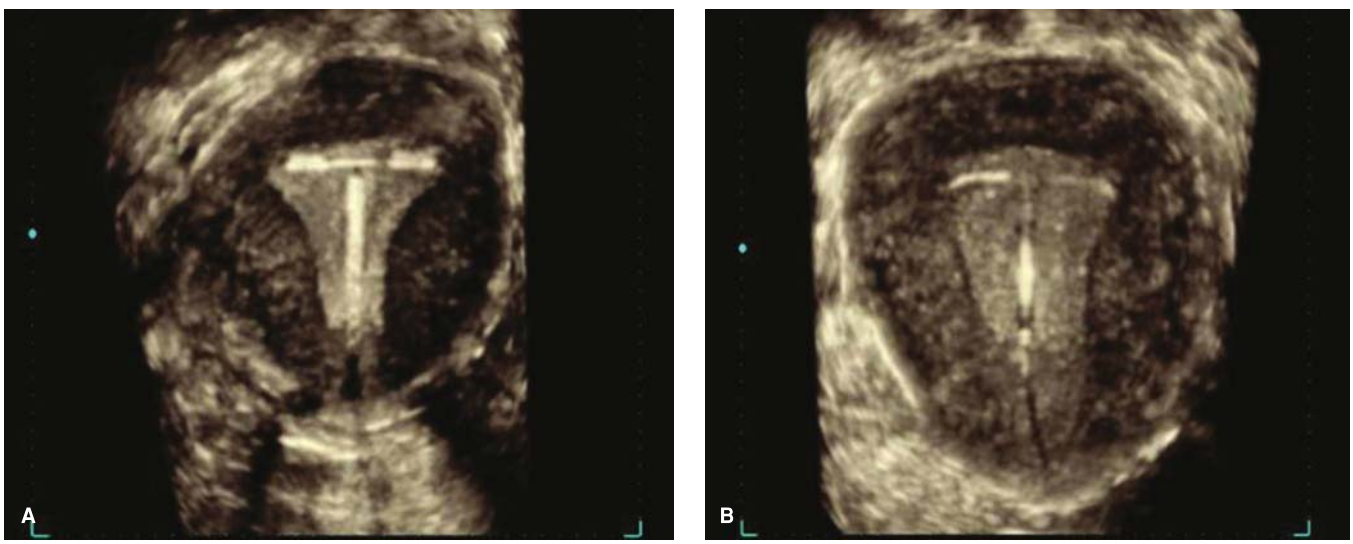

FIGURE 2-11 Intrauterine devices (IUDs). The coronal planes of 3-dimensional sonography best depict the type and positioning of the Copper T 380A IUD (ParaGard) **(A)** and levonorgestrel-containing IUD (Mirena) **(B)** within the endometrial cavity.

estimated from 2-D imaging. It is becoming the preferred ultrasound technique for infertility ovarian evaluation (Nylander, 2017; Peres Fagundes, 2017). Moreover, 3-D sonography can also examine endometrial vascularity and volume to help predict endometrial receptivity prior to ovarian stimulation (Wu, 2003; Zollner, 2012).

For congenital müllerian uterine anomalies, 3-D ultrasound is as sensitive as hysteroscopy and as accurate as MR imaging. It provides detailed images of both endometrial cavity shape and external fundal contour (Bermejo, 2010; Ghi, 2009). Because the uterine horns and fundal contour are displayed clearly in the same plane, müllerian anomalies can be differentiated (p. 41) (Troiano, 2004). This can help preoperative planning.

For pelvic reconstructive surgery indications, 3-D ultrasound can evaluate pelvic floor anatomy and pelvic support. In addition, polypropylene mesh implants appear as echogenic interwoven interfaces with ultrasound. In contrast, these are poorly depicted with radiography or MR imaging. As a result, 3-D vaginal and perineal sonography is now selected for this evaluation (Dietz, 2012, 2017; Fleischer, 2012). However, cranial aspects of mesh or retropubic mesh may be poorly imaged with 3-D ultrasound. For these patients, MR imaging may be helpful.

As a second indication, postprocessing reconstruction in a coronal plane improves views of the urethra and the periurethral tissue, which are inaccessible with 2-D ultrasound techniques. 3-D images are obtained with abdominal transducers using a translabial-transperineal approach or with transvaginal probes using specialized rotational transducers (Dietz, 2007, 2012; Santoro, 2011).

In women with pelvic floor dysfunction, the reconstructed ultrasound images afforded by 3-D ultrasound are particularly useful to quantify the degree of levator ani muscle defects (Dietz, 2017; Hedge, 2017). Perhaps most importantly, 3-D imaging can provide not only anatomic but also dynamic information about the pelvic floor structures, as imaging can be executed with the patient performing the Valsalva maneuver or actively contracting the pelvic floor musculature (Fleischer, 2012).

Contrast-Enhanced Sonography

This newer technique couples IV contrast with traditional sonography. With contrast-enhanced sonography, the density (or signal intensity) of a focal lesion and its density compared with the surrounding normal organ tissue can be enhanced.

Ultrasound contrast agents used intravenously are small, stabilized microbubbles, usually 1 to 10 μm in diameter, and composed of perfluorocarbon or nitrogen gas encapsulated in albumin, phospholipid, or polymer shells. The gas-liquid interface contributes to the echogenicity of the microbubbles. Also, a high impedance mismatch between the microbubbles and adjacent RBCs in the blood vessels causes greater scatter and reflection of the ultrasound sound beam. This heightens the ultrasound signal and thereby increases brightness or echogenicity (Hwang, 2010). The degree of echo enhancement depends on many factors, including microbubble size, contrast agent density, bubble compressibility, and the interrogating ultrasound frequency. The greater the size, density, and compressibility of the agent, the more reflection and echogenicity are elicited (Eckersley, 2002).

For ovarian cancer, contrast-enhanced sonography may highlight tumor neovascularization in developing microscopic tumors (Wu, 2015). In addition, because vascular channels associated with malignancy are often incompetent, the resultant extravasation of RBCs and contrast agent may be detected (Fleischer, 2008). Accordingly, its preoperative interrogation of cervical and endometrial carcinomas can help determine the extent of invasion (Song, 2009; Zheng, 2018).

Other promising clinical applications of contrast-enhanced sonography include monitoring tumor and therapeutic angiogenesis, inflammation assessment, evaluation of ischemia and reperfusion injury, early detection of transplant rejection, and targeted drug delivery (Hwang, 2010; Peng 2016).

Sonoelastography

Elastography is an ultrasound imaging technique that measures tissue stiffness in both physiologic and pathologic states. With this modality, a source of "stress" promotes tissue deformation to assess stiffness (Stoelinga, 2014). For gynecologic imaging, vibration sonoelastography employs low-amplitude, low-frequency shear waves that propagate through the organ of interest. Simultaneously, real-time color Doppler techniques generate an image of tissue movement in response to the external vibrations (Taylor, 2000). For example, if a hard inhomogeneous mass, such as a tumor, lies within a region of soft tissue, the vibration amplitude is decreased at the tumor site.

Potential areas of investigation include distinguishing endometrial polyps from submucous pedunculated myomas, endometrial cancer from benign endometrial thickening, cervical cancer from normal cervical stroma, and leiomyomas from adenomyosis (Stoelinga, 2014, 2018). Moreover, uterine and cervical stiffness during pregnancy may help predict or manage preterm or postterm complications (Xie, 2018).

Focused-Ultrasound Therapy

Ultrasound energy during conventional imaging propagates harmlessly through tissue with little energy being absorbed. This energy is deposited as heat but dissipates by the cooling effects of perfusion and conduction. No harmful effects have been recorded at the intensities used for diagnostic purposes (American Institute of Ultrasound in Medicine, 2009).

If, however, the ultrasound beam carries high energy and is brought into tight focus, this energy is rapidly converted into heat. When target spot temperatures rise above 55°C, proteins are denatured, cells die, and coagulative necrosis follows. In contrast, surrounding tissues are warmed but not to lethal temperatures. In gynecology, this tool offers an option for leiomyoma ablation (Chap. 9, p. 210).

Normal Sonographic Findings

Reproductive Tract Organs

In the reproductive years, a normal uterus measures approximately 7.5 × 5.0 × 2.5 cm but is smaller in prepubertal, postmenopausal, or hypoestrogenized women. Normal uterine stroma returns low-level, uniform echoes, and the endometrial and endocervical canals are indicated by linear echogenic stripes that represent the interfaces between mucus and mucosa (Fig. 2-13). The cervix is best visualized transvaginally with the tip of the probe placed 2 to 3 cm from it. The endocervical canal is a continuation of the endometrial cavity and appears as a thin echogenic line (Fig. 2-14). The vagina is seen as a hypoechoic tubular structure with an echogenic lumen that curves inferiorly over the muscular perineal body at the introitus.

The ovaries are ellipsoid and normally lie in the ovarian fossa with their long axes parallel to the internal iliac vessels (Fig. 2-15). Ovarian volume ranges from 4 to 10 cubic centimeters depending on hormonal status (Cohen, 1990). Ovarian volume is calculated using the formula for an ellipse: $\pi/6 \times (A \times B \times C)$. In this formula, A, B, and C are the ovarian diameters in centimeters, measured in the three different planes.

FIGURE 2-14 Transvaginal sonogram in the sagittal plane of a uterine cervix. An endocervical cyst is seen posterior to the thin, echogenic endocervical canal.

Ovarian follicles appear as spherical anechoic structures within the ovary and may reach a normal size of 3 cm. Normal fallopian tubes are not visible.

Endometrium

Functionally, the endometrium has two main layers: the *stratum basale*, which comprises the densely cellular supporting stroma and varies little with menstrual cycle phase, and the *stratum functionale*, which proliferates during each cycle and partially desquamates at menses. These layers cover the entire cavity.

Sonographically, the endometrium's appearance during the menstrual cycle correlates with the phasic changes in its histologic anatomy. During the follicular phase, when the endometrium is provided estrogen from ovarian folliculogenesis, the stratum basale appears echogenic due to spectral reflections from the mucus-laden glands. In contrast, the stratum functionale is relatively hypoechoic because of its orderly arrangement

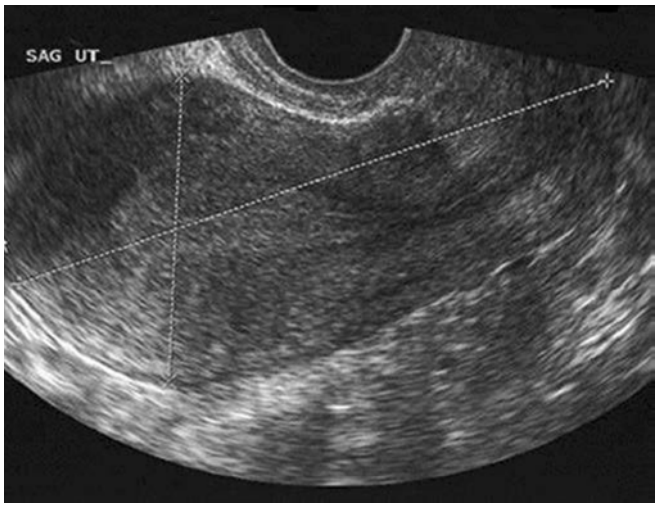

FIGURE 2-13 Transvaginal sonogram in the sagittal plane of an anteverted anteflexed uterus. Calipers demonstrate measurements of the uterine length (+) and the anterior-posterior dimension (×).

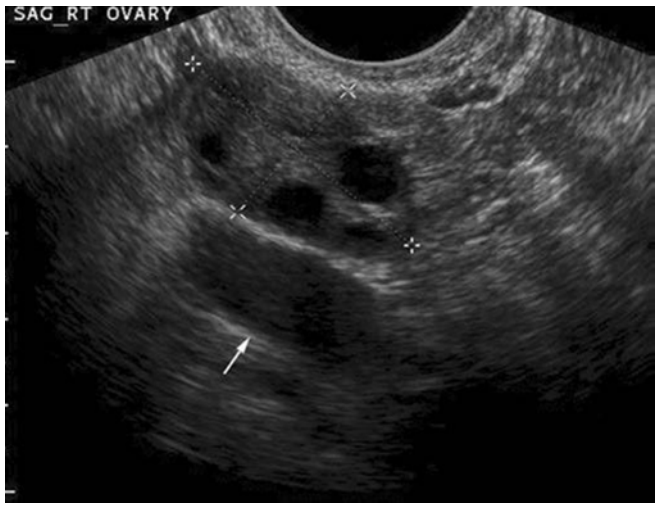

FIGURE 2-15 Transvaginal sonogram in the sagittal plane of an ovary (*calipers*) in a premenopausal woman. The ovary normally lies in the ovarian fossa, anterior to the internal iliac vessel (*arrow*).

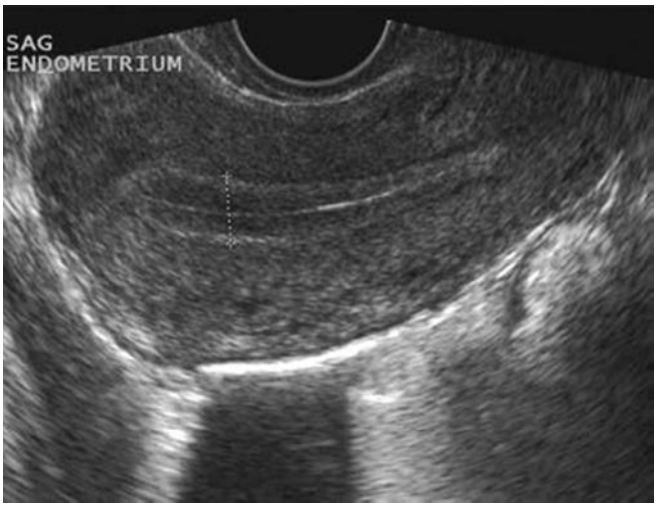

FIGURE 2-16 Transvaginal sonogram in the sagittal plane of a characteristic trilaminar proliferative endometrium. Calipers demonstrate proper measurement of the "double-layer" thickness made of the alternating hyper-hypo-hyperechogenic lines.

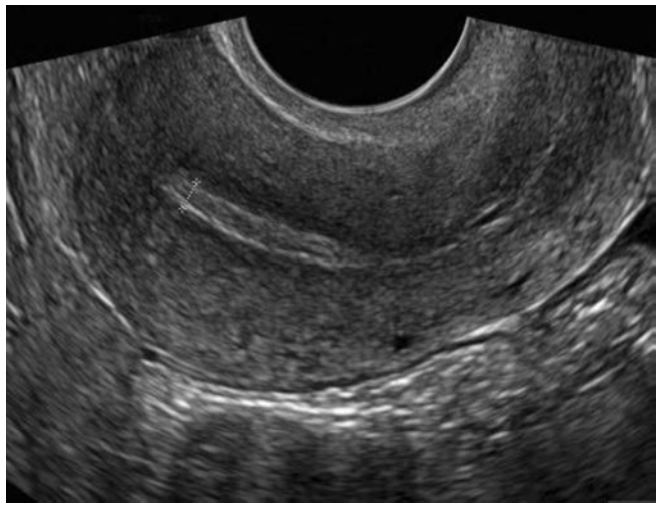

FIGURE 2-18 Transvaginal sonogram in the sagittal plane of a menstrual-phase endometrium, which is marked by calipers.

of glands that lack secretions. The central opposing surfaces of these two endometrial layers manifest as a highly reflective, thin midline strip. Together, the three echogenic lines create the characteristic trilaminar appearance of the proliferative endometrium (Fig. 2-16).

To measure the *endometrial thickness*, one caliper is placed at the echogenic interface of the anterior basale layer and myometrium. The other is positioned at the similar echogenic interface of the posterior basale layer. It thus represents a "double thickness." The hypoechoic halo outside of and adjacent to the endometrium is not included in the measurement, as this is actually the inner compact layer of myometrium. Sonographically, the endometrium is measured from a sagittal or long-axis image of the uterus in the plane where the central endometrial echo is contiguous with the endocervical canal and is distinct from the myometrium. Endometrial thickness correlates approximately with the day of the menstrual cycle up to day 7 or 8.

With ovulation and progesterone production from the corpus luteum, glandular enlargement and secretory vacuoles are seen histologically. During this secretory phase, the endometrium achieves its maximum thickness as the stroma becomes more vascular and edematous. Sonographically, these changes cause the endometrium to appear echogenic (Fig. 2-17).

With menstruation, the endometrium displays as a slightly irregular echogenic interface, which derives from sloughed tissue and blood. The thinnest endometrial measurements are found at the conclusion of menses (Fig. 2-18).

With cessation of estrogen stimulation, the endometrium atrophies, and cyclic sloughing ceases. The postmenopausal endometrium appears thin and uniform (Fig. 2-19).

Pelvic Floor

Sonography is widely used to evaluate pelvic floor anatomy and function (Dietz, 2017). First, various 2-D techniques,

FIGURE 2-17 Transvaginal sonogram in the sagittal plane of a secretory endometrium. The endometrium, which is marked by calipers, has become uniformly echogenic.

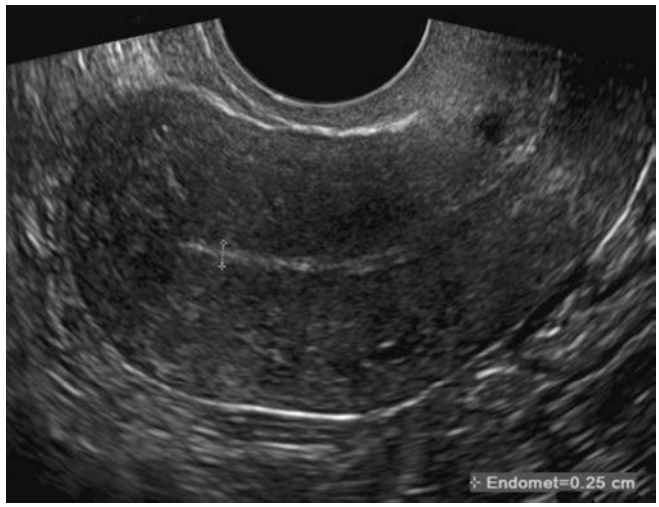

FIGURE 2-19 Transvaginal sonogram in the sagittal plane of an atrophic postmenopausal endometrium, which is marked by calipers.

including transvaginal, transrectal, transperineal, and intraurethral sonography, can display urethral anatomy. In addition, anorectal morphology and the pelvic floor both can be assessed with vaginal sonography using a rotating endorectal probe or standard transvaginal probe (Chap. 25, p. 564). Less commonly, transrectal sonography can assess anal sphincter morphology after childbirth. This method requires special equipment and distention of the anal canal. The technique has limited value in the immediate puerperium and only provides information regarding the anal sphincter. Thus, without levator ani muscle assessment, the posterior compartment is incompletely evaluated.

Perineal sonography requires filling the bladder with approximately 300 mL of saline. With the woman either supine or erect, a 3.5- to 6-MHz curved-array transducer is placed in sagittal orientation to the perineum. This allows real-time imaging of the pubic symphysis, levator ani muscles, urethra, bladder neck, bladder, vagina, rectal ampulla, and anal canal simultaneously and with little transducer manipulation (Dietz, 2017; Schaer, 1995; Vellucci, 2018). Last, 3-D ultrasound is increasingly selected, and evaluation of pelvic anatomy, support, and mesh implants are some indications.

CLINICAL APPLICATIONS OF SONOGRAPHY

Transvaginal sonography is often preferred for early evaluation of pelvic pain, abnormal uterine bleeding, pelvic mass, early pregnancy complications, and infertility practices. Many of these topics and their radiologic characteristics are covered in other chapters. Some remaining important subjects are presented in the following sections.

Intraabdominal Fluid

During general sonographic evaluation of the pelvis, a small amount of free fluid, as little as 10 mL, is commonly present in the posterior cul-de-sac (Khalife, 1998). If free fluid is seen extending to the fundus of the uterus, it is considered moderate in amount. Once identified, moderate free fluid should prompt further evaluation of the paracolic gutters and Morison pouch in the right upper quadrant to assess the fluid's extent (Fig. 2-20). If it fills these areas, then the minimum volume of intraperitoneal fluid approximates 500 mL (Abrams, 1999; Branney, 1995). Large amounts of anechoic free peritoneal fluid generically described as *ascites* suggest a volume status abnormality or an infectious or inflammatory etiology. Free fluid that contains low-level echoes or echogenic debris is consistent with hemoperitoneum with clot, such as with a ruptured hemorrhagic ovarian cyst or ectopic pregnancy.

Focused assessment with sonography for trauma (FAST) is a limited sonographic examination directed solely to help diagnosis intraperitoneal bleeding. With FAST, four specific areas are imaged: perihepatic (right upper quadrant), perisplenic (left upper quadrant), pelvis, and pericardium. For intraperitoneal free fluid identification, FAST is a rapid, noninvasive, bedside test and has significant advantages compared with diagnostic peritoneal lavage or with CT. However, FAST has a significant false-negative rate (Scalea, 1999). This stems in part from examination being carried out early when only a small amount of free fluid may have collected in dependent portions of the peritoneal cavity.

Malignant Ovarian Characteristics

Sonography is commonly the initial and often the only imaging procedure performed during pelvic and ovarian mass evaluation, as most can be correctly categorized based on grayscale and Doppler ultrasound characteristics. Found in Table 10-2 (p. 221), recommendations from a Society of Radiologists in Ultrasound consensus conference summarize a reasonable management approach to asymptomatic ovarian and other adnexal cysts imaged sonographically (Levine, 2010).

Sonography is the best preoperative diagnostic technique to determine the malignant potential of an ovarian mass

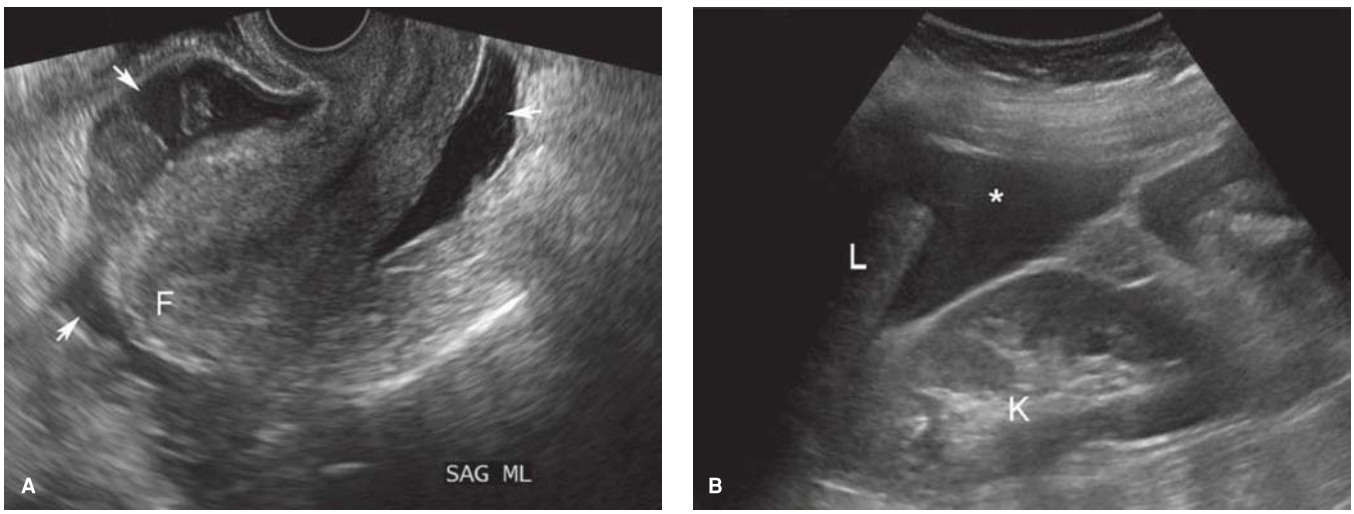

FIGURE 2-20 Hemoperitoneum. **A.** In this transvaginal image, a large amount of free fluid (*arrows*) is seen in the posterior cul-de-sac, above the fundus of the uterus, and in the anterior cul-de-sac. Floating clot is also seen in the anterior cul-de-sac. **B.** Transabdominal image of Morison pouch in the right upper quadrant. Free fluid, corresponding to the dark anechoic area (*asterisk*), is visualized between the liver edge (*L*) and the kidney (*K*), which suggests a large-volume hemoperitoneum.

(Twickler, 2010). To this end, morphologic scoring systems based on number and thickness of septa, presence and number of papillations, and proportion of solid tissue within the mass have been proposed to standardize findings (DePriest, 1993; Sassone, 1991). When size, morphology, and structure of adnexal masses are combined with color Doppler and spectral analysis of flow signals, the specificity and positive predictive value of sonographic diagnosis are increased (Buy, 1996; Fleischer, 1993; Jain, 1994; Kinkel, 2000). The International Ovarian Tumor Analysis (IOTA) Group has developed the most accurate mathematic model to date to calculate the malignancy risk of an adnexal mass based on sonographic features (Timmerman, 2005, 2016). We use the Ovarian Tumor Index developed by Twickler and colleagues (1999) at our institution.

Neovascularity secondary to angiogenesis within a malignant neoplasm increases color Doppler flow signals. These new vessels are abnormal, lack smooth muscle, and contain multiple arteriovenous shunts. Consequently, low-impedance flow is expected with such masses (see Fig. 2-4) (Kurjak, 1992; Weiner, 1992). Moreover, most malignant lesions appear well-vascularized and display flow signals in both peripheral and central regions—including within septations and solid tumor areas. In contrast, most benign tumors appear poorly vascularized. Of Doppler parameters, the color content of a tumor probably reflects tumor vascularity better than any other. The overall impression of this vascularity reflects both the number and size of vessels and their functional capacity. The IOTA group scoring system uses this subjective semiquantitative assessment of flow to describe the vascular features of ovarian masses (Ameye, 2009; Timmerman, 2005). A four-point color score is used to describe tumor blood flow only within septa and solid portions of the mass (Timmerman, 2000). However, because of overlap of vascular parameters between malignant and benign neoplasms, a firm differential diagnosis based on spectral Doppler evaluation alone is not possible (Valentin, 1997).

Pelvic Inflammatory Disease

With acute salpingitis, pelvic sonography is commonly performed as part of an acute pain assessment. However, large studies evaluating its sensitivity, specificity, or overall usefulness for PID diagnosis are lacking (Romosan, 2014). Sonographic findings vary according to disease severity, and in early infection, anatomy may appear normal. With progression, early nonspecific findings include free pelvic fluid, endometrial thickening, endometrial cavity distention by fluid or gas, and indistinct borders of the uterus and ovaries. Enlarged ovaries with increased numbers of small cysts—a "polycystic ovary appearance"—can correlate with PID. With treatment, this ovarian enlargement resolves (Cacciatore, 1992).

Sonographic findings of the fallopian tubes are the most striking and specific landmarks of PID (Fig. 2-21). Although normal tubes are rarely seen unless surrounded by ascites, tubal wall inflammation allows visualization with sonography. As the lumen occludes distally, the tube distends and fills with pus. Various appearances result. The tube may become ovoid or pear shaped, filling with fluid that may be anechoic or echogenic. The tubal wall becomes thickened, measuring ≥5 mm, and

FIGURE 2-21 Transvaginal sonogram of an inflamed, dilated fallopian tube (*arrow*) demonstrating thickened tubal walls, incomplete septa, and intratubal fluid.

incomplete septa are common as the tube folds back on itself. If the distended tube is viewed in cross section it may demonstrate the cogwheel sign, due to thickened endosalpingeal folds (Timor-Tritsch, 1998). Typically, the swollen fallopian tubes extend posteriorly into the cul-de-sac, rather than extending cephalad and anterior to the uterus as large ovarian tumors tend to do. Fluid-debris levels are often visualized in the dilated tubes, and rarely, gas-fluid levels or echogenic bubbles of gas are seen. Color and power Doppler show increased flow from hyperemia in the walls and in incomplete septa of the inflamed tubes (Tinkanen, 1993).

As the disease progresses, the ovary can become involved. When an ovary adheres to the fallopian tube, but is still visualized, it is called a *tuboovarian complex*. In contrast, a *tuboovarian abscess (TOA)* results from a complete breakdown of ovarian and tubal architecture such that the separate structures are no longer identified (Fig. 2-22). If the contralateral side was

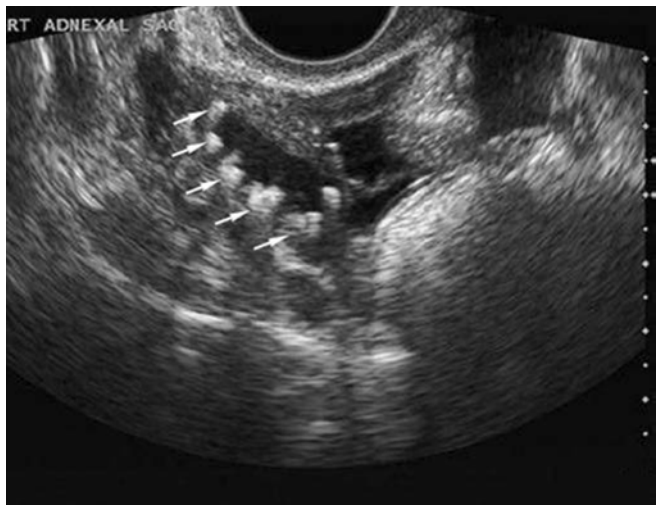

FIGURE 2-22 "Beads on a string" sign. The echogenic mural nodules shown here (*arrows*) within this tuboovarian abscess are thought to represent flattened and fibrotic endosalpingeal folds of the inflamed fallopian tube.

not affected initially, it may become so. When both tubes are inflamed and occluded, the entire complex typically acquires a U-shape as it fills the cul-de-sac, extending from one adnexal region to the other. The lateral and posterior uterine borders become obscure, and individual tubes and ovaries cannot be distinguished. In women not responding to medical therapy, sonography or CT can be used to guide percutaneous or transvaginal drainage of TOAs.

Findings of chronic PID include hydrosalpinx. As discussed in Chapter 10 (p. 229), several sonographic findings such as its tubular shape, incomplete septa, and hyperechoic mural nodules can help to distinguish a hydrosalpinx from other cystic adnexal lesions. If color flow is detected in a hydrosalpinx, it tends to be less exuberant than flow seen in acute PID. Molander and colleagues (2002) found a higher pulsatility index in patients with a chronic hydrosalpinx (1.5 ± 0.1) than with acute PID (0.84 ± 0.04).

A small number of women with prior PID may have a peritoneal inclusion cyst. These form when ruptured ovarian cyst fluid is trapped around the ovary by adhesions. This diagnosis is suspected if the ovary is surrounded by fluid loculations created by thin septations.

Infertility

For female infertility evaluation, sonography can help identify abnormal pelvic anatomy, detect contributory pathology, and evaluate cyclic physiologic uterine and ovarian changes. During treatment, sonography aids ovarian surveillance to guide management.

Sonography easily demonstrates many uterine defects that may affect both gamete passage and ovum implantation. TVS can display submucous leiomyomas and polyps, but their relationships with the endometrial surface are better seen with SIS. As a screening tool for cavity evaluation in this setting, SIS appears to be twice as accurate as HSG or TVS (Seshadri, 2015). Many infertility specialists now incorporate SIS as a first-line screening tool for uterine evaluation before embryo transfer in women undergoing IVF, ovum donation, or IVF-surrogacy. Intrauterine adhesions, also termed *synechiae*, are displayed as hypoechoic lines disrupting the echogenic endometrium. These are more definitively seen during SIS as echogenic bands extending from one endometrial surface to the other (Fig. 2-23).

TVS also can help detect congenital uterine anomalies related to infertility or early spontaneous abortion. The addition of 3-D techniques raises sonographic test performance to a level similar to that of HSG, laparoscopy, and MR imaging. Thereafter, MR imaging is used to characterize and evaluate complicated or equivocal cases, especially preoperatively (p. 49).

Of abnormalities, a fusion anomaly, such as uterus didelphys, can be accurately diagnosed by sonography. In this setting, two divergent uterine horns are separated by a deep fundal cleft, and a wide angle separates the two endometrial cavities (Fig. 2-24). In contrast, bicornuate and septate uterine anomalies are less confidently differentiated by traditional 2-D TVS techniques. Ideally, the angle between the two endometrial cavities is $\geq 105°$ for bicornuate uterus, but $\leq 75°$ for septate uterus. The fundal shape shows a >1-cm notch for bicornuate uterus, but a <1-cm notch for septate uterus (Reuter, 1989).

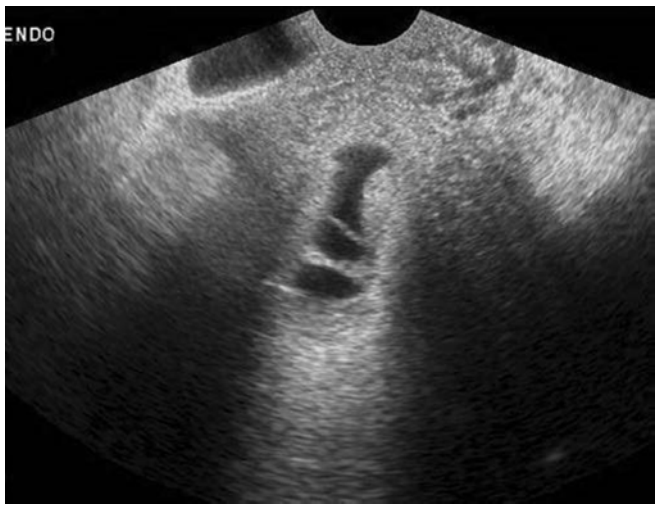

FIGURE 2-23 Asherman syndrome. Transvaginal saline-infusion sonography demonstrates echogenic intrauterine synechiae.

However, in many cases, the distinctions between bicornuate and septate uteri are subtle. In a 3-D coronal plane, relationship between the uterine fundus and the *intercornual line*—the line joining both horns of the uterine cavity—can be measured to aid diagnosis (Fig. 2-25). Similarly, arcuate versus partial septate uteri can be correctly differentiated using quantitative measurements of the endometrial cavity fundal indentation depth in the coronal plane. Combining 3-D TVS findings with SIS provides accuracy up to 90 percent to distinguish the two anomalies. Although MR imaging is frequently employed, 3-D sonography is considered by many to be the best noninvasive method for distinguishing between these uterine anomalies (Bermejo, 2010).

A unicornuate uterus without a rudimentary horn is seen as a small, well-formed elliptical uterus that deviates to one side. The fundus is concave. With 3-D imaging, the unicornuate uterus has a classic "banana" configuration (Fig. 2-26). In 65 percent of cases, however, the unicornuate uterus is associated with a

FIGURE 2-24 Uterus didelphys. Transvaginal sonogram in the transverse plane best depicts the two completely separate uterine horns. A gestational sac is evident in the right uterus.

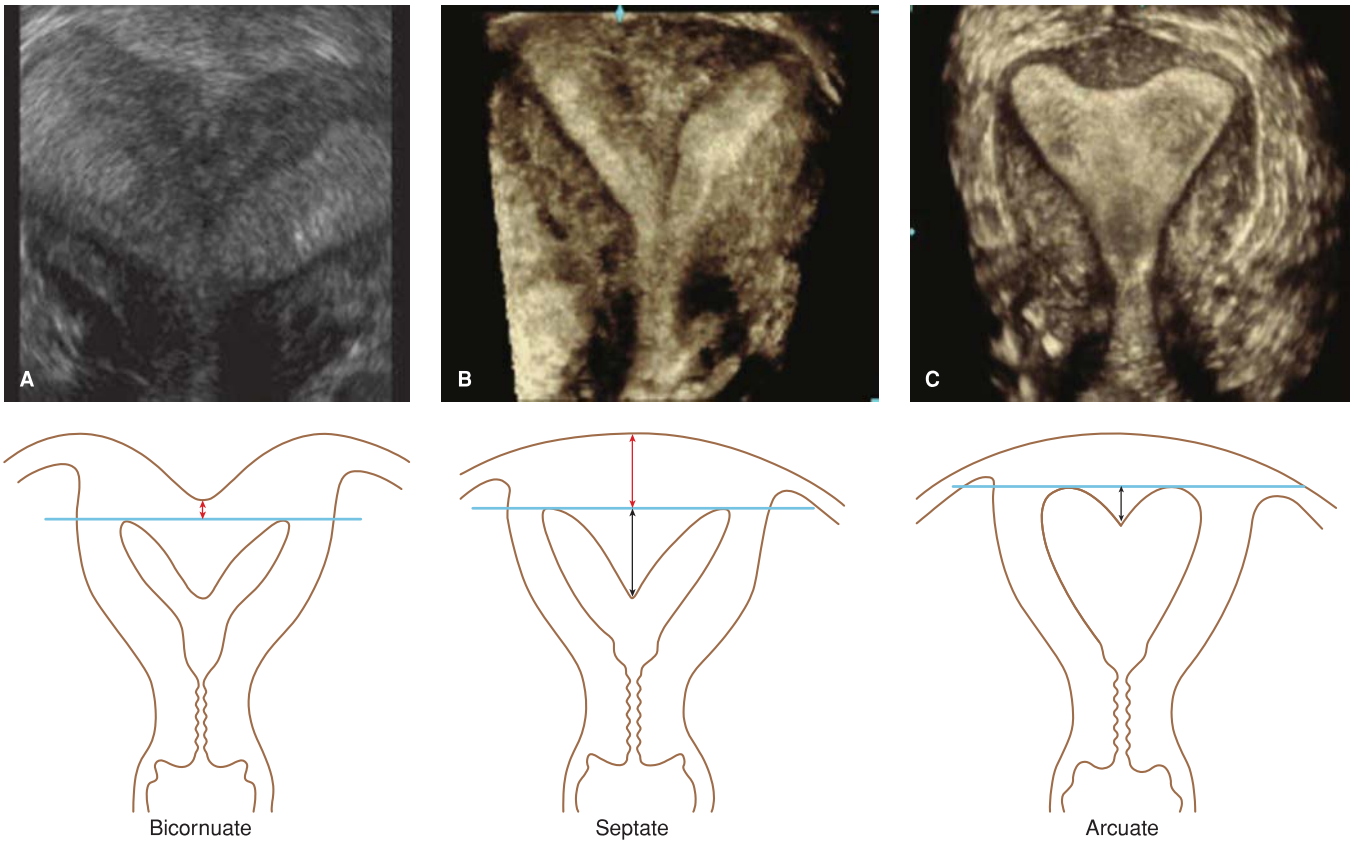

FIGURE 2-25 Three-dimensional (3-D) images of müllerian uterine anomalies in the coronal plane and corresponding diagrammatic uteri. **A.** Bicornuate uterus. This 3-D rendered image demonstrates a concave external fundal contour that dips to a point near the intercornual line. This point lies no further than 5 mm from the intercornual line (*red line*), which characterizes a bicornuate uterus. The 5-mm defining distance, either above or below the intercornual line, is used to differentiate bicornuate and septate uteri. **B.** Septate uterus. This image depicts the narrow angle between the two small endometrial cavities, which is characteristic of a septate uterus, and shows a normal uterine serosal contour. This contour extends >5 mm (*red line*) above the intercornual line, which is characteristic of a septate uterus. The septum ends at the uterine isthmus and does not extend into the cervix. Thus, this anomaly is properly termed *subseptate*. **C.** Arcuate uterus. This image illustrates the normal uterine contour and obtuse angle of the endometrial cleft that is characteristic of an arcuate uterus. The cleft extends <15 mm (*black line*) below the intercornual line, which is characteristic of arcuate uterus. In diagram B, the distance (*black line*) between the cleft and intercornual line is >15 mm, which reflects a septate uterus. This 15-mm defining distance is used to differentiate arcuate and septate uteri.

FIGURE 2-26 Unicornuate uterus. The coronal plane of 3-dimensional sonography illustrates the classic "banana" configuration. A gestational sac is seen within the endometrial cavity.

rudimentary horn, which is difficult to recognize sonographically (Fig. 19-11, p. 420) (Jayasinghe, 2005). A rudimentary horn is often misdiagnosed as a uterine or adnexal mass. Complete evaluation of these cases often requires MR imaging. With most uterine anomalies, especially if unilateral, proper positioning of the kidneys should be documented with transabdominal imaging. This is because of the close link between reproductive and urinary anomalies. Last, in women with complex anomalies associated with vaginal agenesis or imperforate hymen, hematocolpos is often seen and frequently is associated with hematometra or hematosalpinx.

Pelvic endometriosis is a prominent cause of infertility, and sonography is the most common imaging procedure in suspected cases. It is most effective to evaluate endometriotic ovarian cysts, and its capability to detect small implants and adhesions is limited. Endometriomas exhibit various sonographic appearances, the most frequent being a pelvic mass with a thick wall and diffuse low-level echoes within the cyst (Fig. 11-4, p. 239). Magnetic resonance imaging is more specific than sonography for identifying endometriomas, and thus,

it is indicated in cases with unclear anatomy sonographically (Fig. 11-5, p. 240).

Sonography is invaluable for infertility treatment surveillance. First, folliculogenesis both in normal and stimulated cycles can be monitored. Observation of a developing follicle and ovulation prediction allow optimal timing for postcoital testing, human chorionic gonadotropin (hCG) administration, intercourse, insemination, and ovum collection. At ovulation, the dominant follicle usually disappears, and fluid is observed in the cul-de-sac. At the follicular site, the corpus luteum appears as an irregular oval containing a small quantity of fluid, internal echoes, and a thick wall. In general, blood flow in the ovulating ovary diminishes throughout the menstrual cycle. At ovulation, blood flow velocities dramatically rise in vessels surrounding the corpus luteum because of neovascularization and are seen as low-impedance waveforms. In women undergoing in vitro fertilization (IVF), low ovarian vessel impedance may correlate directly with pregnancy rates (Majeed, 2018).

Sonography can be used to guide interventional maneuvers such as oocyte retrieval and transfer of embryos into the endometrial cavity (Figs. 21-10 and 21-12, p. 465). In stimulated cycles, sonographic detection of too many follicles allows withholding of hCG induction to prevent ovarian hyperstimulation syndrome (Fig. 21-4, p. 457). If this develops, sonography is used to grade disease severity through measurements of ovarian size, detection of ascites, and analysis of renal flow resistances.

Ultrasound Beyond the Pelvis

Ultrasound is used throughout the body. It is often the initial tool in radiologic evaluation, given its lack of ionizing radiation, low cost, and availability. In the abdomen, common indications for solid organ evaluation include abdominal and flank pain, jaundice, hematuria, organomegaly, or palpable mass. Abnormal blood tests, including elevated liver function tests and creatinine, also may be indications for an abdominal ultrasound. Typically, a limited or right upper quadrant ultrasound includes the liver, gallbladder, common bile duct, pancreas, and right kidney. A complete abdominal ultrasound adds the spleen, left kidney, and images of the aorta and inferior vena cava in the upper abdomen. Ideally, a patient has fasted prior to sonographic evaluation of the abdomen. This minimizes bowel gas and permits adequate gallbladder distention. A renal ultrasound focuses on the kidneys, proximal collecting systems, and urinary bladder. Outside of the abdomen and pelvis, a gynecologist may select ultrasound to evaluate superficial structures, like the thyroid gland and breasts. Breast imaging is discussed fully in Chapter 13 (p. 279).

Compression Sonography

Compression sonography, often combined with color Doppler sonography, is the initial test currently used to detect deep-vein thrombosis (DVT) (Hanley, 2018; Needleman, 2018). Leg vein interrogation is divided into two components. First, the groin and thigh are examined with the patient supine. Then, the popliteal region is evaluated with the patient sitting or lying on her side with the thigh abducted and externally rotated. Some institutions also evaluate the calf veins. Impaired visibility, noncompressibility, and the typical echo pattern of a thrombosed vein confirm the diagnosis (Fig. 2-27).

Examination of the femoral, popliteal, and calf trifurcation veins in symptomatic patients is more than 90-percent sensitive and greater than 99-percent specific for proximal DVT (Davis, 2001). Moreover, in 220 patients with suspected DVT, Lensing and coworkers (1989) compared compression sonography with contrast venography, which is the gold standard for DVT detection. Both the common femoral and popliteal veins were fully compressible—no thrombosis—in 142 of 143 patients who had a normal venogram (99-percent specific). All 66 patients with proximal vein thrombosis had noncompressible femoral or popliteal veins or both (100-percent sensitive).

For detecting calf vein thrombosis, compression sonography is significantly less reliable. Eventually, isolated calf thromboses extend into the proximal veins in up to a fourth of cases. They do so within 1 to 2 weeks of presentation and thus are usually detected by serial sonographic compression examinations (Bates, 2004). The safety of withholding anticoagulation for those symptomatic patients who have a normal compression examination has been established (Birdwell, 1998; Friera, 2002). Importantly, normal venous sonographic findings do not necessarily exclude pulmonary embolism (PE) because the thrombosis may have already embolized or because it arose from deep pelvic veins, which are inaccessible to sonographic evaluation (Goldhaber, 2004).

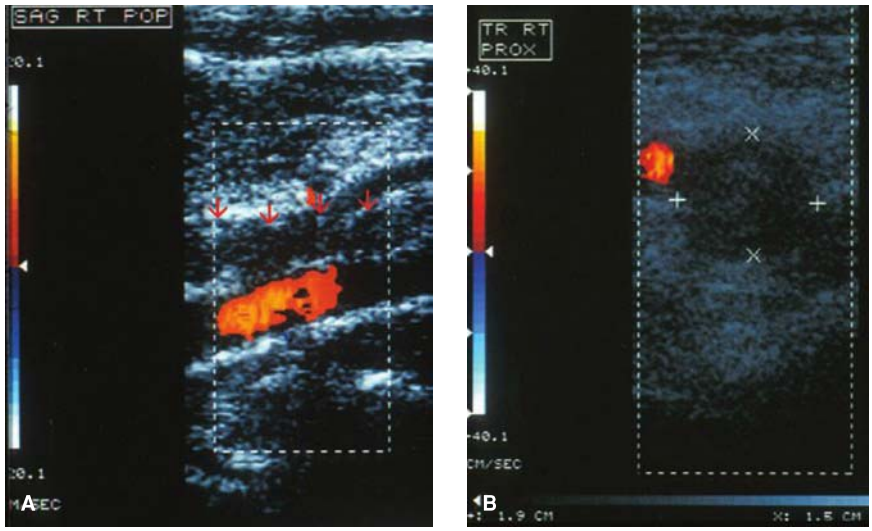

FIGURE 2-27 Sagittal **(A)** and transverse **(B)** images from a lower extremity. Color Doppler ultrasound study in a woman with popliteal vein thrombosis. **A.** Red arrows demarcate the popliteal vein with no flow suggesting clot in the lumen, which sits above the artery demonstrating normal flow as evidenced by the red color map. **B.** The transverse image shows the large size of the vein due to the thrombus (*cursors*), as well as normal flow in the artery, evidenced by the red color map.

RADIOGRAPHY

Radiographs are used in gynecologic practice in a manner similar to other medical specialties. Of frequently used studies, the *acute abdominal series* includes an upright radiograph of the chest to exclude free air under the diaphragm, an upright film of the abdomen to exclude air-fluid levels within bowel loops, and a supine image to measure bowel loop widths. It is commonly selected as an initial modality if bowel obstruction or perforation is a concern. Importantly, images from those with recent laparotomy or laparoscopy often show expected subdiaphragmatic air. In contrast, a single supine radiograph of the abdomen is called a KUB (kidneys, ureters, and bladder). It may help identify an extrauterine location of a missing IUD or a collecting-system stone.

In women with gynecologic malignancies, radiographs also may be informative. Examples are chest radiographs to screen for pulmonary metastases during cancer staging and during surveillance after initial treatment. As discussed in the next sections, several specialized radiographic procedures are especially useful or specific for gynecology.

Intravenous Pyelography

Excretory urography, also called *intravenous pyelography (IVP)*, provides serial images of the urinary tract. The initial radiograph, termed a *scout film*, helps identify radiopaque urinary calculi. IV contrast is then administered, and the concentrating function of the proximal tubules renders renal parenchyma radiodense within 1 to 3 minutes. This *nephrogram phase* displays renal size, contour, and axis. Next, a radiograph obtained 5 minutes after agent injection depicts contrast excreted into the collecting system. During this *pyelogram phase,* the calyces and proximal ureters are evaluated for symmetry and excretion promptness. Serial imaging is obtained as the more distal collecting system and bladder are opacified by contrast, and a final postvoid radiograph completes the series.

Up to 5 to 10 percent of women have an allergic reaction to iodide during IVP, and 1 to 2 percent of reactions are life threatening. In addition, hyperosmolar ionic contrast can be nephrotoxic because of direct tubular insult and ischemic injury. Notably, women with diabetes, renal impairment, and congestive heart failure are at high risk for this contrast nephrotoxicity. As alternatives, nonionic low and isoosmolar iodinated contrast media carry a five- to 30-fold lower incidence of allergic reactions and are less nephrotoxic (Mishell, 1997). Because of this improved safety profile, most centers no longer use intravascular hyperosmolar ionic contrast.

Preoperatively, IVP may be selected to identify urinary anomalies coexistent with congenital reproductive tract defects or confirm lower urinary tract compression by an adjacent pelvic mass. However, many preoperative IVPs have been replaced with multiphasic CT urography protocols performed on multislice CT scanners (Beyersdorff, 2008). For example, as it now is a suitable element of cervical cancer staging, many clinicians substitute CT imaging for IVP in initial cervical cancer evaluation. Of value, CT allows the cervix, parametria, uterus, adnexa, retroperitoneal lymph nodes, liver, and ureters to be imaged concurrently.

For suspected nephrolithiasis, the American College of Radiology recommends primary evaluation using noncontrast CT given its superior sensitivity for these stones (Moreno, 2015). To evaluate hematuria, noncontrast combined with contrast-enhanced CT images (CT urography) is most appropriate because of its improved sensitivity for renal and urothelial masses. Although IVP has higher in-plane spatial resolution, the current recommendations are to move immediately to initial one-step CT evaluation as CT is frequently needed regardless of IVP results to delineate abnormalities (Cowan, 2007, 2012). That said, IVP may still play a role, especially in resource-poor areas, in postoperative patients, and in those for whom radiation exposure is ideally minimized. Specifically, IVP delivers an average adult effective dose of 1 to 10 mSv, whereas CT urography carries an average adult effective dose of 10 to 30 mSv (Moreno, 2015).

Voiding Cystourethrography and Positive Pressure Urethrography

These radiographic procedures are used to evaluate the female urethra. Voiding cystourethrography (VCUG) is performed by placing a small catheter into the urinary bladder to instill contrast media. If present, diverticula that open into the urethra will fill with contrast. In cases of suspected vesicovaginal or urethrovaginal fistula, the contrast trail connecting the two involved structures is seen.

In comparison, MR imaging permits superior visualization of urethral abnormalities and is more sensitive than VCUG or positive pressure urethrography (PPUG) for delineating diverticula with complex structure (Chou, 2008; Neitlich, 1998). For this reason, VCUG is currently more often used to evaluate lower urinary tract injury, such as fistulas, and patients with prolonged urinary retention, incontinence, or suspected vesicoureteral reflux.

Described in more detail in Chapter 26 (p. 583), PPUG use has declined. This stems mainly from fewer technicians trained to complete the study, difficulty finding appropriate equipment, and the higher sensitivity of MR imaging.

Hysterosalpingography

This radiographic imaging technique is typically used during infertility evaluations to assess the endocervical canal, the endometrial cavity, and the fallopian tube lumina by injecting radiopaque contrast material through the cervical canal (Chap. 20, p. 438). An average HSG study is performed in 10 minutes, involves approximately 90 seconds of fluoroscopic time, and has an average radiation exposure to the ovaries of 0.01 to 0.02 Gy. As discussed previously (p. 32), hysterosalpingo-contrast sonography is used by some initially in place of HSG to assess tubal patency.

Hysterosalpingography is performed between cycle days 5 and 10. During this time, cessation of menstrual flow minimizes infection and the risk of flushing an ovum from the fallopian tube following ovulation. The test causes cramping, and an NSAID taken 30 minutes prior to the procedure may limit discomfort. To begin, a designated balloon-tipped injection catheter or acorn cannula is introduced just beyond the internal os in

the lower endometrial cavity, as this location is more comfortable for the patient. However, the catheter may also be positioned just beyond the external os within the endocervical canal if necessary. A paracervical block may be indicated in selected patients, such as those with cervical stenosis. Because rapid injection may cause tubal spasm, slow contrast injection of usually no more than 3 to 4 mL of contrast medium allows a clear outline of the uterine cavity. Generally, few radiographic views are needed: a preliminary view before injecting contrast, a view showing uterine cavity filling, and the third demonstrating spill of contrast from the tubes into the peritoneal cavity. An additional image with the catheter deflated and pulled back into the endocervical canal will typically be obtained at the conclusion of the examination to evaluate the lower uterine cavity and internal os.

A normal endometrial cavity is usually triangular or sometimes T-shaped in the anteroposterior (AP) projection (Fig. 20-6, p. 439). In a lateral view, it is oblong. The contour of the endometrium is usually smooth. It occasionally has polypoid filling defects that can be isolated or diffuse and can be difficult to distinguish from endometrial polyps or hyperplasia. Inadvertent injection of air bubbles introduces artifact. In these instances, SIS is often later obtained to further interrogate the endometrial cavity.

Contraindications to HSG include acute pelvic infection, active uterine bleeding, pregnancy, and iodine allergy. HSG complications are rare but can be serious. Of these, the overall risk of acute pelvic infection serious enough to require hospitalization is <1 percent but can reach 3 percent in women with prior pelvic infection (Stumpf, 1980). In patients with no history of pelvic infection, HSG is performed without prophylactic antibiotics. If HSG demonstrates dilated fallopian tubes, doxycycline, 100 mg orally twice daily for 5 days, is given to reduce the incidence of post-HSG PID. In patients with a history of pelvic infection, doxycycline can be administered before the procedure and continued if dilated fallopian tubes are found (American College of Obstetricians and Gynecologists, 2018). Pelvic pain, uterine perforation, and vasovagal reactions also may occur. From the contrast, allergic reaction and entry into the vascular system from high injection pressure are potential risks.

Selective Salpingography

In some cases, it is not possible to distinguish whether tubal blockage seen by HSG is caused by anatomic occlusion or tubal spasm. Described in Chapter 44 (p. 1067), hysteroscopic tubal cannulation can further clarify and treat many cases of proximal tubal occlusion. Alternatively, transcervical selective salpingography and tubal catheterization (SS-TC) under fluoroscopic guidance is another suitable procedure. Similar to HSG, it is performed during the follicular phase. The tubal catheter is forwarded through the cervix and advanced by tactile sensation to the tubal ostium. The position of the catheter is checked fluoroscopically, and water- or oil-soluble contrast is injected. If the obstruction is overcome, the tubal contour is outlined with contrast agent. If the proximal tubal obstruction persists, a guide wire is threaded through the inner cannula of the catheter, advanced toward the obstruction, and gently manipulated to overcome the blockage. The guide wire is then withdrawn, and contrast medium is injected through the catheter to confirm patency. This fluoroscopic tool is effective at diagnosing and treating proximal tubal blockage, as discussed in Chapter 21 (p. 459) (Capitanio, 1991; Thurmond, 1991).

Bone Densitometry

Depending on its mineral density, bone absorbs x-rays to different degrees. Because of this, bone density can be determined, and most measurements provide site-specific information. However, these studies do not assess current or past bone remodeling rates. Thus, sequential density measurements are necessary to monitor rates of bone loss over time (Kaplan, 1995).

Dual-energy x-ray absorptiometry (DEXA) measures integral bone (cortical and trabecular bone) mineral density and is the preferred method to diagnose osteoporosis and monitor treatment (Fig. 22-9, p. 488). DEXA employs two x-ray beams of differing energy levels and accurately measures bone density in the hip and spine. The spine is commonly scanned between the first and fourth lumbar vertebrae. DEXA measurements are accurate; radiation dose is low (<5 mrem); and patient acceptability is high because the procedure time is usually only 5 to 15 minutes (Jergas, 1993). Of disadvantages, DEXA is a 2-D technique that cannot distinguish between cortical and trabecular bone. In addition, bone spurs, aortic calcifications, and arthritis may falsely elevate reported bone density.

Quantitative computed tomography (QCT) evaluates bone mineral in high-turnover trabecular bone. QCT uses multiple x-rays to provide a cross-sectional view of the vertebral body. As the rate of turnover in trabecular bone is nearly eight times that in cortical bone, this technique can detect early metabolic changes in this highly vulnerable tissue. It provides a volumetric density, which is an advantage in situations in which DEXA may underestimate bone mineral density (Damilakis, 2007). Although its precision is excellent, it has never been validated for World Health Organization (WHO) criteria and is not routinely used as a screening modality.

COMPUTED TOMOGRAPHY

This procedure involves multiple exposures of thin x-ray beams that are translated to 2-D axial images, termed a *slice*, of the particular area of interest. Multiple slices of the targeted body part are obtained along its length. Multiple-channel helical CT, also called *spiral CT*, allows for continuous acquisition of images in a spiral and the potential for image reformatting in multiple planes. This technique is much faster and permits images to be manipulated for analysis after they have been acquired. Many variables affect radiation dose, especially slice thickness and number of cuts obtained. If a study is performed with multiple phases of contrast, each added phase or acquisition multiplies the total patient dose of radiation.

IV contrast enables superior evaluation of solid organ parenchyma and vasculature. By adding IV contrast, masses become more obvious due to density differences. Dedicated thin-slice evaluation of vasculature, termed CT angiography (CTA) can be done throughout the body. Traditional (fluoroscopic) angiography is still performed, but cross-sectional CT imaging provides

accurate information and is technically easier. As discussed earlier, IV nonionic low and isoosmolar iodinated contrast media can induce nephrotoxicity and are used with caution in patients with or with risks for renal insufficiency. IV hydration before and after an examination can help reduce contrast-induced nephrotoxicity. One option is 0.9-percent saline at 100 mL/hr beginning 6 to 12 hours before imaging and continuing 4 to 12 hours after the examination (American College of Radiology, 2018).

Oral contrast may enhance CT images if gastrointestinal disease is sought or if bowel must be differentiated from adjacent structures. Positive oral contrast is most frequently used and is dense (white) on scan images. Patients with documented allergies to IV contrast are rarely allergic to oral contrast. Intraluminal contrast in the rectum or urinary bladder also is dense (white) and can be used to address a specific concern, such as rectovaginal fistula or bladder injury, respectively.

Normal Pelvic Anatomy

The uterus appears as a homogenous, soft tissue oval or triangle situated posterior to the bladder (Fig. 2-28). The uterine walls enhance after IV contrast. However, unlike sonography and MR imaging, the endometrium is poorly delineated by CT imaging. The cervix also may not enhance like the remainder of the uterus, and the inner stromal layer typically enhances less than the outer stromal layer (Yitta, 2011). The endocervical canal, which can be identified by MR imaging, is indistinct using CT imaging. The lateral margins of the cervix can typically be differentiated from parametrial fat because of differences in density. However, CT is not sensitive for parametrial involvement in the setting of cervical cancer (Hricak, 2005). Imaging of the vagina and vulva is very limited with CT. Typically, the ovaries are relatively hypodense, vary in appearance and position, and are usually situated lateral to the uterus.

Imaging Following Gynecologic Surgery

CT is well suited to diagnose potential complications of gynecologic procedures. For ureteral injuries, CT with IV contrast or CT urography is useful. To detect obstruction or injury, CT images are obtained after the kidneys have excreted the contrast and have opacified the collecting systems. High-density (white) contrast that abruptly stops within the ureter suggests obstruction. With ureteral disruption, contrast may flow freely from the injury site or may form an encapsulated collection, a *urinoma* (Titton, 2003).

For bladder injury, CT cystography may be informative. For this, the bladder is retrograde filled with 300 to 400 mL of dilute iodinated contrast by gravity drip. This is followed by helical CT of the bladder with multiplanar reformations (Chan, 2006). The technique is sensitive and specific for diagnosis of extraperitoneal and intraperitoneal bladder rupture and can also demonstrate fistulas connecting to the bladder (Jankowski, 2006; Yu, 2004).

CT also outperforms conventional radiography and barium studies for diagnosing bowel complications, such as small bowel obstruction (Maglinte, 1993). For characterizing an abdominal-pelvic fluid collection such as abscess or hematoma, CT with intravenous and oral contrast may be more helpful than other imaging tools (Fig. 3-8, p. 71) (Gjelsteen, 2008).

Gynecologic Malignancy

In most instances, sonography is the preferred initial method of evaluating the female pelvis. For additional information, MR imaging is now often preferable to CT imaging because it avoids radiation exposure and iodinated IV contrast, provides excellent soft-tissue contrast, and displays pelvic structures in multiple planes. However, in many settings, the greater availability of CT is another advantage compared with MR imaging. In addition, to evaluate and monitor gynecologic malignancies, CT imaging is probably the most frequently used imaging technique. Although its sensitivity for intraperitoneal metastases is limited, CT can estimate bulky metastases, such as in women with advanced ovarian cancer.

FIGURE 2-28 Computed tomography (CT) of the female pelvis in the axial plane demonstrates the normal uterus (*arrows*) as well as cysts in the left ovary (*curved arrows*).

MAGNETIC RESONANCE IMAGING

With this technology, images are constructed based on the radiofrequency signal emitted by hydrogen nuclei after they have been "excited" by radiofrequency pulses in the presence of a strong magnetic field. The radiofrequency signal emitted has characteristics called *relaxation times*. These include the T1 relaxation time and the T2 relaxation time. The signal intensity of one tissue compared with another, that is, the contrast, can be manipulated by adjusting parameters of the acquisition. Examples are varying the elapsed time between applications of radiofrequency pulses, which is called *repetition time,* and the time between a radiofrequency pulse and sampling the emitted signal, called the *echo delay time*.

Sequences with a short repetition time and short echo delay time are called *T1-weighted*. Sequences with a long repetition time and long echo delay time are regarded as *T2-weighted*. As examples, the hydrogen molecules in a water-containing area have longer relaxation times than those in a solid tissue. Thus, on T1-weighted images, urine in the bladder will appear dark or have low signal intensity. On T2-weighted images, the same urine

will appear bright or have high signal intensity. By manipulating multiple parameters and imaging planes, MR imaging can achieve superior soft-tissue contrast. The strength of the magnetic field within the bore of the magnet is measured in tesla (T) (1 tesla = 10,000 gauss). For reference, the earth's magnetic field is approximately 0.5 gauss. Most clinical magnets used for MR imaging are 1.5 to 3 T or 15,000 to 30,000 gauss.

Technique

The standard imaging technique for the pelvis includes both T1- and T2-weighted sequences that are acquired in at least two planes, usually axial and sagittal. The T2-weighted sequence provides detailed definition of internal organ architecture, such as the uterus, vagina, and ovaries. The T1-weighted sequence clearly delineates organ boundaries and surrounding fat, allows optimal visualization of lymph nodes, and is necessary for tissue and fluid content characterization.

To aid accurate diagnosis, highly paramagnetic gadolinium-based contrast agents (GBCA) are often administered prior to imaging. The most frequently used GBCA types are extracellular agents administered intravenously. Gadolinium shortens the T1 relaxation time of adjacent protons. This increases signal intensity on T1-weighted images to enhance information regarding tissue vascularity (Gandhi, 2006). Side effects are rare, and MR contrast can be used even in those with prior reactions to other contrast agents (American College of Radiology, 2018). MR contrast is given in concentrations and doses significantly lower than that used in CT imaging, undergoes renal excretion within 24 hours, and is safe for patients with mildly compromised renal function. Of note, the Food and Drug Administration recommends caution in administering IV GBCA to patients with moderate to end-stage renal disease due to the rare but serious risk of developing nephrogenic systemic fibrosis (NSF). The risks and benefits of using GBCA are discussed by the requesting physician and radiologist. Written informed consent from the patient is obtained if GBCA use is required for those with a severely diminished glomerular filtration rate. Providing hemodialysis immediately after administration of GBCA for patients in this renal category for NSF prevention has not been proven.

In addition to intravascular GBCA, water-soluble ultrasound gel can be placed endoluminally in the vagina or the rectum to better delineate anatomy. This technique can also aid detection of fistulas or congenital vaginal septa (Gupta, 2016).

Additional imaging parameters include fat saturation to detect bulk fat and opposed-phase imaging to highlight microscopic fat. Diffusion-weighted imaging (DWI) with quantitative measurement of apparent diffusion coefficient (ADC) characterizes proton movement in tissues. Highly cellular tissues restrict random Brownian motion and yield a high DWI signal and low ADC value. This cellularity information can help identify tumor, abscess, and lymph nodes (Moore, 2014).

Safety

To date, harmful or mutagenic effects have not been reported from MR imaging at field strengths used clinically, that is, 3 T or lower. Additionally, the American College of Radiology considers MR imaging in pregnancy to be risk free, regardless of trimester. Using the ALARA (as low as reasonably achievable) principle, imaging during pregnancy is typically limited to 1.5 T. Moreover, GBCA is not used routinely in pregnancy due to the theoretic risk of toxic gadolinium ion dissociation into the amnionic fluid (American College of Radiology, 2017).

TABLE 2-1. Safety of MR Imaging with Some Implanted Devices

Device	Safe (S), Conditional (C), or Unsafe (U)	
	1.5 T	3 T
Intrauterine Devices		
Paragard	S	C
Mirena	S	S
Skyla	—	C
Tubal Occlusion Devices		
Essure	S	C
Adiana (Silicone)	S	S
Adiana (Radiopaque)	S	C
Filshie Clips	S	C
Hulka (Clemens) Clip	S	C
Implants		
Implanon/Nexplanon	S	S
Saline or silicone breast	S	S
Tissue expander with non-magnetic injection site	S	—
Tissue expander with magnetically localizable injection site	U	U
Biopsy Needles/Markers		
Localization wires	U	U
Biopsy needles	U	U
Coaxial needles	U	U
Breast biopsy markers (e.g., HydroMARK)	S	C

Some, but not all, devices preclude MR imaging. For example, many implanted devices unique to women can be safely imaged (Table 2-1). Contraindications to entering the MR environment include mechanically, electrically, or magnetically activated implanted devices such as internal cardiac pacemakers, neurostimulators, cardiac defibrillators, electronic infusion pumps, and cochlear implants. Certain intracranial aneurysm clips and any metallic foreign body in the globe of the eye contraindicate scanning. Before the patient enters the MR environment, radiology personnel should obtain documentation of the type of patient implant (manufacturer, model and type) and verify its MR safety rating.

Use in Gynecology

Although sonography is widely used for suspected gynecologic disease, MR imaging may add information when sonographic

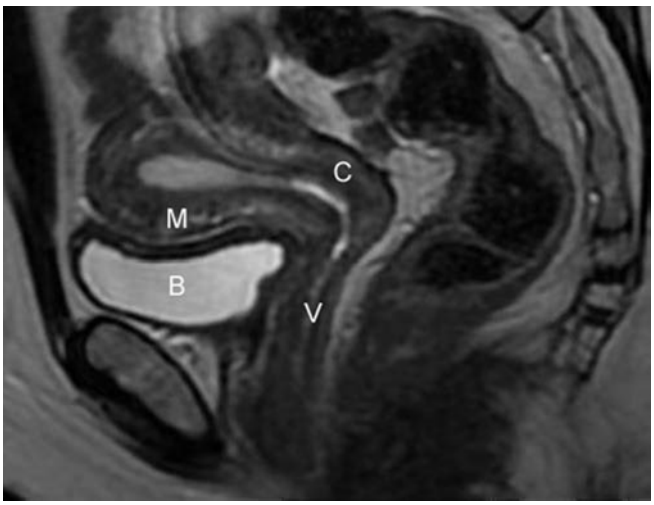

FIGURE 2-29 Sagittal T2-weighted magnetic resonance (MR) image of a normal uterus and cervix (C). B = bladder; M = myometrium; V = vagina.

findings are equivocal. Specifically, its multiplanar imaging, superior soft-tissue contrast, and large field of view are distinct MR imaging advantages. Accordingly, common indications for MR imaging include distorted pelvic anatomy, large masses that are poorly delineated with sonography, indeterminate cases of adenomyosis, and endometrial disorders in poor surgical candidates. In some instances, pelvic MR imaging may help tailor management. Also, MR imaging can be selected for primary evaluation and subsequent surveillance of pelvic malignancies.

Normal Findings

The pelvic organs show generally moderate to low signal intensity on T1-weighted images. T2-weighted images of the menstrual uterus depict a high-signal-intensity endometrium; contiguous low-signal-intensity inner myometrium, which is the junctional zone; and a moderate-signal-intensity outer myometrium (Fig. 2-29) (McCarthy, 1986).

The cervix can be distinguished from the uterine body by its prominent fibrous stroma, which has an overall lower signal intensity. The internal architecture of the cervix is seen on T2-weighted images as central high signal intensity (endocervical glands and mucus) surrounded by low signal intensity (fibrous stroma) and peripheral moderate signal intensity (smooth muscle intermixed with fibrous stroma) (Lee, 1985). Similarly, T2-weighted images of the vagina display central high-signal-intensity mucosa and mucus, which is surrounded by a low-signal-intensity muscular wall (Hricak, 1988). Ovaries are normally seen on the T2-weighted sequence as stroma with moderately high signal intensity that contains very high-signal-intensity follicles (Dooms, 1986). The fallopian tubes are not typically visualized. Hormonal status influences the MR appearance of all structures and reflects associated physiologic changes.

Benign Disease

Leiomyomas

For suspected leiomyomas, the initial imaging technique is sonography. However, its limited field of view, image resolution that declines with increasing patient body fat, and distorted anatomy from large or multiple myomas are potential hindrances (Wolfman, 2006). False-negative rates may reach 20 percent with TVS, and tumors measuring <2 cm are routinely missed (Gross, 1983). Thus, MR imaging is used when TVS findings are equivocal or nondiagnostic (Ascher, 2003). For conservative myoma treatment, the effects of GnRH agonist therapy to shrink tumor volume can be quantified with MR imaging (Lubich, 1991). Moreover, MR imaging is warranted before UAE or focused-ultrasound myoma treatments and often selected prior to hysteroscopic myoma resection. In these cases, imaging verifies leiomyoma location, seeks tumor qualities that portend outcome success or failure, and excludes other causes of patient symptoms such as unsuspected malignancy or indeterminate intracavitary masses (Cura, 2006; Rajan, 2011).

Shown in Figure 2-30, leiomyomas have a variable but characteristic MR appearance and thus can be differentiated from

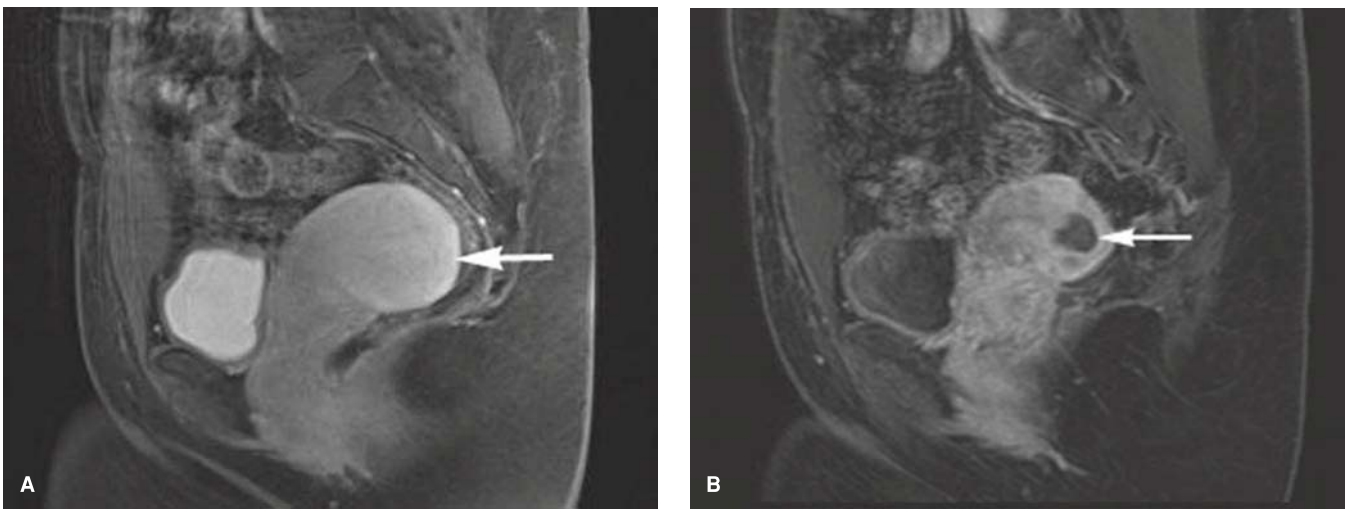

FIGURE 2-30 **A.** Sagittal T1-weighted post-contrast image demonstrates a 5.6-cm enhancing leiomyoma at the uterine fundus (*arrow*). **B.** Sagittal T1-weighted post-contrast image of the same patient 2 months after uterine artery embolization demonstrates lack of enhancement in the fibroid and significant interval decrease in size (now measuring 2 cm).

adenomyosis or adenomyoma with 90-percent accuracy (Mark, 1987; Togashi, 1989). This is important when myomectomy is considered. Leiomyomas, even those as small as 0.5 cm, are best seen on T2-weighted images and appear as round, sharply marginated masses with low signal intensity relative to the myometrium. Tumors >3 cm often are heterogeneous because of varying degrees and types of degeneration (Hricak, 1986; Yamashita, 1993). With MR imaging, multiplanar views allow for accurate tumor localization as subserosal, intramural, or submucosal. Moreover, pedunculated myomas and their bridging stalk can be defined. Of myoma types, intramural or subserosal leiomyomas are frequently circumscribed by a high-signal-intensity rim that represents edema from dilated lymphatics and veins.

Of treatment options, magnetic resonance–guided focused ultrasound (MRgFUS), also called *magnetic resonance high-intensity focused ultrasound (MR-HIFU)*, directs high-power ultrasound pulses—*sonications*—into the myoma. Without MR guidance, focused-ultrasound therapy is hampered by imprecise beam targeting. Fortunately, excellent soft-tissue resolution with MR imaging enables precise tissue targeting. Moreover, MR imaging can measure accurate, near real-time thermometry. This permits power adjustments to reach adequate treatment temperatures yet minimize thermal injury. Pulse duration lasts generally 15 seconds, and a cooling interval is inserted between pulses. The average procedure duration approximates 3.5 hours (Hindley, 2004). This has improved with updated devices. Outcomes, candidate selection, and comparisons with UAE are described in Chapter 9 (p. 209).

Congenital Anomalies

Discussed in Chapter 19 (p. 419), müllerian duct anomalies comprise a spectrum of developmental malformations. In the past, full evaluation required laparoscopy, laparotomy, HSG, and hysteroscopy. These invasive techniques were largely replaced by MR imaging, which has an accuracy of up to 100 percent (Carrington, 1990; Fielding, 1996).

MR imaging is particularly adept at differentiating septate and bicornuate uteri, which is imperative as these two have differing clinical implications and surgical management. IV contrast is not routinely needed. If a vaginal septum is suspected clinically, ultrasound gel placed within the vagina prior to imaging may be helpful (Gupta, 2016). T2-weighted images and coronal planes are typically the most informative. With these, the septate uterus generally displays a convex fundal contour. The bicornuate uterus typically has a significant fundal notch >1 cm. However, any notch depth within 5 mm of the intercornual line qualifies for bicornuate (Behr, 2012). The endometrial cavities of a bicornuate uterus have a normal width and communicate. Although a less-reliable marker, an intercornual distance typically measures >4 cm with a bicornuate uterus (Carrington, 1990; Fedele, 1989).

With a septate uterus, a fibrous septum divides the two uterine horns. Collagen has low signal intensity on both T1- and T2-weighted images, whereas the intervening myometrium of a bicornuate uterus has high signal intensity on T2-weighted images. The fundal contour of the septate uterus can be convex, flattened, or mildly concave, but if present, the fundal notch lies >5 mm above the intercornual line (Behr, 2012). Also in contrast to the bicornuate uterus, the intercornual distance of a septate uterus is not increased, and thus each uterine cavity is smaller than usual (Carrington, 1990; Forstner, 1994).

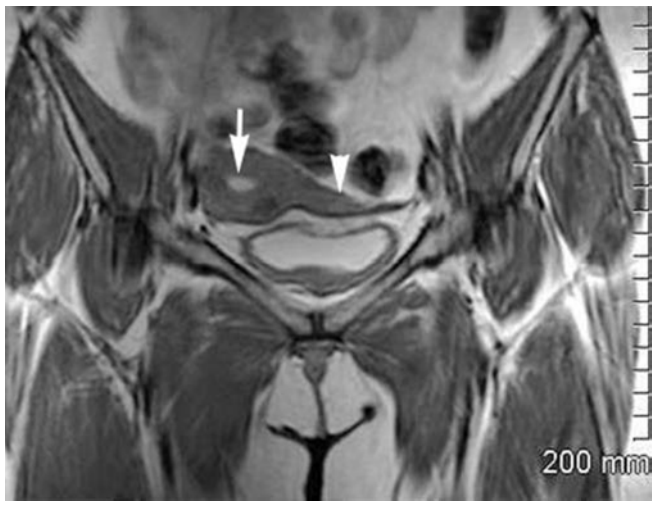

FIGURE 2-31 Unicornuate uterus. This coronal T2-weighted image demonstrates a protrusion of myometrial tissue from the left lateral uterine body (*arrowhead*). It is isointense to myometrium but does not demonstrate normal uterine zonal anatomy. Specifically, endometrium (*arrow*) is noted in the developed right uterine horn but not in the left rudimentary horn.

MR imaging also offers detailed evaluation of a unicornuate uterus, especially in evaluation for a rudimentary horn (Fig. 2-31). On MR imaging, if endometrial tissue is present within a rudimentary horn, zonal anatomy will be preserved. Moreover, communication of an endometrium-containing rudimentary horn is of considerable clinical importance (Chap. 19, p. 422). In a menstruating woman, a noncommunicating horn containing endometrium will often be evident as a hematometra when the cavity becomes distended with blood. MR imaging can also identify uterine didelphys, agenesis, or hypoplasia.

Other Gynecologic Indications

MR imaging is equivalent or superior to sonography to diagnose adenomyosis and has a sensitivity of 88 to 93 percent and a specificity of 66 to 99 percent (Ascher, 1994; Dueholm, 2001; Reinhold, 1996). Compared with sonography, MR imaging reliably diagnoses adenomyosis, particularly focal adenomyomas, in the setting of concomitant pathology such as leiomyomas. In addition, MR imaging reproducibility allows accurate treatment monitoring (Reinhold, 1995).

With adenomyosis, the low-signal-intensity junctional zone (inner myometrium) on T2-weighted images measures >12 mm (Fig. 2-32). A normal junctional zone can be up to 8 mm, and measurements from 8 to 12 mm are considered indeterminate (Novellas, 2011). Low-signal-intensity areas of adenomyosis often contain internal ovoid or punctate foci of increased signal on both T1- and T2-weighted images. These foci are nests of ectopic endometrium with dilated endometrial glands, with or without hemorrhage (Reinhold, 1995, 1996). Contrast

FIGURE 2-32 Sagittal T2-weighted magnetic resonance image of a uterus with diffuse adenomyosis. Adenomyosis is shown as circumferential thickening of the junctional zone.

administration does not increase the diagnostic accuracy for adenomyosis (Outwater, 1998).

For polyps and endometrial hyperplasia, TVS and SIS are common diagnostic tools. MR imaging may be helpful if these modalities are nondiagnostic in a patient who is a poor surgical candidate for direct endometrial sampling. However, distinguishing intracavitary myomas and endometrial polyps can be problematic with MR imaging if necrosis and inflammation are present.

For diagnosing ovarian endometriomas, MR imaging offers 98-percent specificity, which is similar to TVS. These cysts show imaging characteristics of old blood products that include "shading" signal loss on T2-weighted images and a hyperintense signal on T1-weighted images (Chamie, 2011). However, MR imaging differs from TVS in that it can provide evaluation for endometriosis in locations that are not easy to access sonographically or laparoscopically, especially in the setting of advanced disease. For diagnosing pelvic deep infiltrating endometriosis, MR imaging has a sensitivity of 90 percent, specificity of 91 percent, and accuracy of 91 percent (Bazot, 2004). Additional endometriosis features include the stellate margins of fibrotic plaques, tethering, and obliteration of normal pelvic spaces. On T1-weighted images, foci with hyperintense signals aids diagnosis of multifocal lesions involving the bladder, rectum, or ureters.

For other adnexal masses, MR imaging can further characterize anatomy if sonography is nondiagnostic or inconclusive. MR imaging frequently provides added information regarding soft-tissue composition and the origin and extent of pelvic pathology that may be nongynecologic. Although both sonography and MR imaging are highly sensitive for the detection of adnexal malignancy, MR imaging is slightly more specific (Adusumilli, 2006; Jeong, 2000; Yamashita, 1995).

Gynecologic Malignancies

For cervical cancer, imaging can be a component of strict clinical staging (Chap. 30, p. 661). Also, MR imaging is an excellent adjunct for preoperative assessment of gynecologic neoplasms. Its superior soft-tissue contrast and ability to image directly in multiple planes allow evaluation for local tumor extension and lymphadenopathy.

Although CT imaging is typically used for assessment of nodal disease and distant metastases, MR imaging consistently outperforms clinical and CT evaluation of cervical cancer in the assessment of local tumor extension (Choi, 2004; Hricak, 1996, 2007). Current recommendations for MR imaging of cervical cancer include tumors with a transverse diameter >2 cm based on physical examination, endocervical or predominately infiltrative tumors that cannot be accurately assessed clinically, and women who are pregnant or have concomitant uterine lesions that make evaluation difficult (Ascher, 2001; Hricak, 2007). When the extent of parametrial and sidewall invasion is unclear clinically, MR imaging can play an important role as it has a 95- to 98-percent negative predictive value for parametrial invasion (Hricak, 2007; Subak, 1995).

For endometrial carcinoma, surgery is currently the most accurate preoperative staging method. MR imaging may assess the degree of myometrial and cervical extension, which can affect the planned hysterectomy type, extent of lymph node dissection, and decision to provide neoadjuvant intracavitary radiation (Boronow, 1984; Frei, 2000). MR imaging has 92-percent accuracy in staging endometrial cancer, and 82-percent accuracy in assessing myometrial invasion depth (Hricak, 1987). Thus, MR imaging is often considered if lymph node metastases are likely, such as from a high-grade tumor; with papillary or clear cell histology; with cervical invasion; or if multifactorial assessment of myometrial, cervical, and lymph node involvement is required (Ascher, 2001).

For ovarian neoplasms, MR imaging is reserved for evaluation when TVS or CT scanning is indeterminate or nondiagnostic, or in cases with a desire to minimize ionizing radiation (Kang, 2018). However, in a Society of Radiologists in Ultrasound consensus statement, MR imaging was recommended to assess simple ovarian cysts >7 cm. This factored sonography's limitations in detecting mural nodules in larger ovarian masses (Ekerhovd, 2001; Levine, 2010). MR imaging also can better determine adnexal mass origin as uterine, ovarian, or nongynecologic. For those of the ovary, MR imaging helps clarify whether the mass is neoplastic or functional and is malignant or benign. MR imaging of an adnexal mass ideally includes gadolinium-enhanced images to assess tumor vascularity and incorporates fat-saturation techniques to differentiate blood from fat (Ascher, 2001). Although histology cannot be diagnosed, imaging findings that are suspicious for malignancy include enhancing solid components, thick septations, nodules, or papillary projections.

Sensitivity of MR imaging for detecting adnexal pathology ranges from 87 to 100 percent, which is comparable to sonography and CT scanning (Siegelman, 1999). The advantages of MR imaging compared with CT scanning in the evaluation of suspected ovarian cancer include its superior contrast resolution and greater sensitivity for detecting uterine invasion, extrapelvic peritoneal and lymph node metastases, and tumor extension to omentum, bowel, bone, and vessels (Low, 1995; Tempany, 2000). However, MR imaging has a lower sensitivity for implants <1 cm compared with CT (Sala, 2013).

Urogynecology

Pelvic floor evaluations previously performed fluoroscopically are now more often performed with MR imaging. MR imaging provides detailed soft-tissue evaluation of the female urethra, levator ani muscles, and adjacent pelvic structures (Pannu, 2002). Contrast agents placed in the vagina, rectum, and/or bladder can enhance imaging.

Functional data also can be obtained. For example, dynamic MR imaging is completed as the patient performs the Valsalva maneuver. With MR defecography, the patient both performs Valsalva maneuver and defecates rectal contrast (ultrasound gel) during rapid cine acquisitions. Protocols vary significantly from center to center, and upright open MR units are not universally available. We employ supine MR defecography at our institution (Khatri, 2015; Kumar, 2014). MR defecography can evaluate patients with pelvic organ descent, incontinence, constipation, and defecatory dysfunction. It may add information prior to complex pelvic floor reconstruction or after failed previous repairs (Macura, 2006).

NUCLEAR MEDICINE

Nuclear medicine examinations are used similarly in the gynecologic patient as in other medical specialties. Small amounts of radioactive material are ingested or injected to diagnose, and at times treat, various diseases. Thyroid studies use radioactive iodine to assess or ablate function. Bone scans may be elected to seek metastatic disease. Various renal scans can offer information regarding renal function, perfusion, and possible obstruction. Ventilation-perfusion (V/Q) scans can help identify pulmonary emboli. Controversy remains regarding whether pulmonary artery CTA or V/Q scan is most appropriate in pulmonary emboli evaluation. The V/Q scan does not use nephrotoxic agents and is often preferred in those with renal insufficiency. However, radiopharmaceuticals are not always readily available, and thus pulmonary artery CTA is frequently employed.

Positron emission tomography (PET) uses short-lived radiochemical compounds to serve as tracers for measuring specific metabolic processes suggestive of malignancy or infection (Juweid, 2006). This enables detection of early cancer biochemical anomalies that precede structural changes. With FDG-PET, a radiolabeled analogue of glucose, 2-[^{18}F]fluoro-2-deoxy-D-glucose (FDG), is injected intravenously and is taken up by metabolically active cells such as tumor cells. PET provides a poor depiction of detailed anatomy, thus scans are frequently read side-by-side or fused with CT scans. The combination allows correlation of metabolic and anatomic data. As a result, current PET scanners are now commonly integrated with CT scanners, and the two scans can be performed during the same session.

PET/CT has become a vital clinical tool, particularly for cancer diagnosis and management. The most common PET radiochemical tracer used clinically is FDG. This tracer highlights areas of accelerated glycolysis, which is common in neoplastic cells (Goh, 2003).

Several studies have demonstrated high sensitivity and specificity of FDG-PET for the initial staging of cervical cancer. This may be most valuable in patients with no evidence of extrapelvic metastatic disease by MR or CT imaging (Gjelsteen, 2008; Park, 2005). The ability of FDG-PET imaging to assess nodal status in cervical cancer has both prognostic and therapeutic implications (Fig. 2-33). Prior to lymph node radiation treatment planning, the added anatomic data obtained with PET/CT can be used to guide intensity-modulated radiotherapy

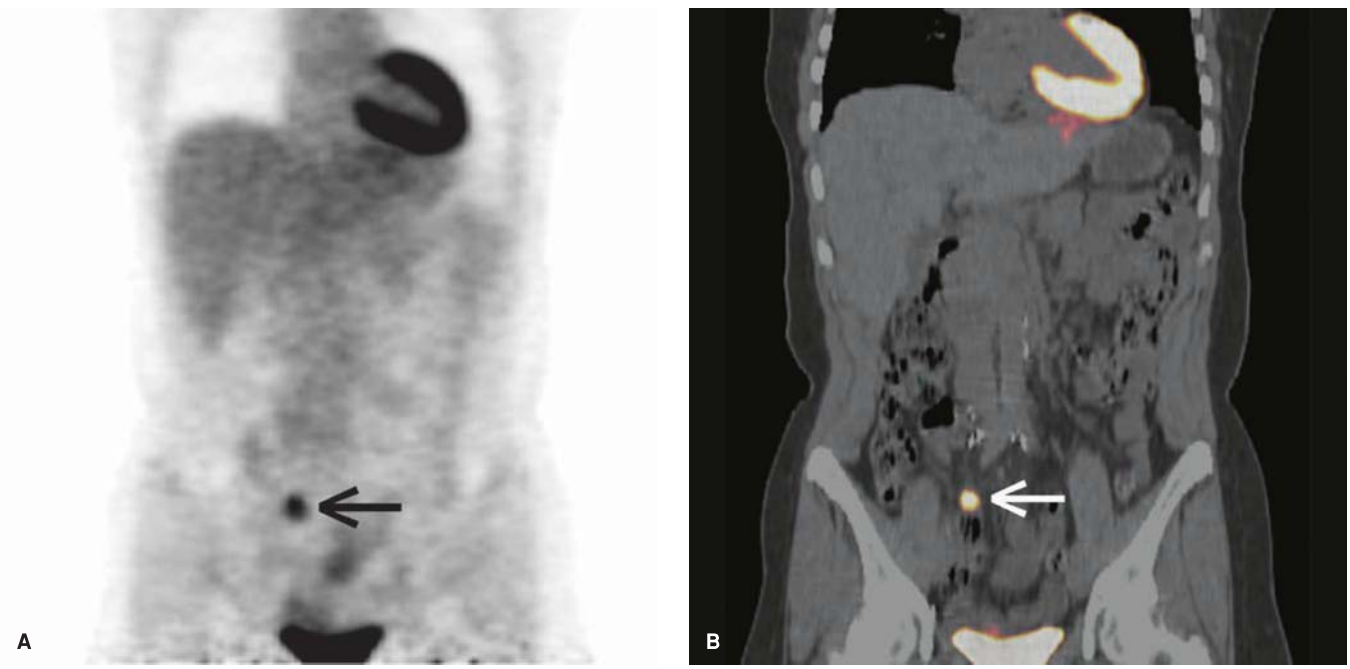

FIGURE 2-33 Positron emission tomography (PET) **(A)** and PET-computed tomography (PET-CT) fusion **(B)** images of a woman with recurrence of ovarian cancer. Arrows demarcate abnormal uptake of tracer in the pelvis that represented a 1-cm lymph node. The biopsy of this lymph node revealed recurrent ovarian cancer. (Chap. 28, p. 612). This significantly reduces the amount of radiation delivered to surrounding normal structures (Havrilesky, 2003; Wong, 2004).

INTERVENTIONAL RADIOLOGY

In gynecology, procedures often provided by interventional radiologists include image-guided biopsy or drainage. In those with advanced cervical cancer, percutaneous nephrostomy may be needed to preserve renal function or to decompress an infected collecting system. UAE is a vascular intervention that employs angiography to delineate the uterine arteries. Once catheterized, each artery is injected with embolic particles to occlude uterine vasculature. Discussed in Chapter 9 (p. 209), UAE can provide definitive independent treatment of uterine leiomyomas. Although adenomyosis was initially thought to be a contraindication for UAE success, studies are now showing durable treatment efficacy (Kim, 2007). Given the frequent concomitant presence of adenomyosis and uterine leiomyomata, treatment success and improvement in symptoms also have been reported in populations with both diseases after UAE (Froeling, 2012). Rarely, UAE may be selected to control severe uterine bleeding in women who are not considered surgical candidates.

NORMAL VAGINAL FLORA

The vaginal flora of a normal, asymptomatic, reproductive-aged woman includes multiple aerobic, facultative anaerobic, and obligate anaerobic species. Of these, anaerobes predominate and outnumber aerobic species approximately 10 to 1 (Bartlett, 1977). These bacteria exist with the host in a symbiotic relationship, which is alterable depending on the microenvironment.

Certain bacterial species normally found in vaginal flora have access to the upper reproductive tract. The female upper reproductive tract is not sterile, and the presence of these bacteria does not indicate active infection (Hemsell, 1989; Spence, 1982). Together, these findings illustrate the potential for infection following gynecologic surgery and the need for antimicrobial prophylaxis.

Vaginal pH

Typically, the vaginal pH ranges between 4 and 4.5. This is due in part to gram-positive aerobic *Lactobacillus* species producing lactic acid, fatty acids, and other organic acids. Other bacteria also can add organic acids from protein catabolism, and anaerobic bacteria donate by amino acid fermentation.

Glycogen, which is present in healthy vaginal mucosa, provides nutrients for many vaginal ecosystem species and is metabolized to lactic acid (Boskey, 2001). Glycogen content within vaginal epithelial cells normally diminishes after menopause and is low in childhood. As a result, postmenopausal women not receiving estrogen replacement and young girls have a lower prevalence of *Lactobacillus* species and less acid production compared with that of reproductive-aged women. This leads to a rise in vaginal pH. For menopausal women, hormone replacement therapy restores vaginal lactobacilli populations, which protect against vaginal pathogens (Dahn, 2008).

Altered Flora

Changing other elements of the vaginal ecology may alter the prevalence of various species and may lead to infection. With the menstrual cycle, transient changes in flora are observed. These are predominantly during the first days of the cycle and are presumed to be associated with hormonal changes (Keane, 1997). Menstrual fluid can serve as a nutrient source for several bacterial species, resulting in their overgrowth. The role of this in the development of upper reproductive tract infection following menstruation is unclear, but an association may be present. For example, women symptomatic with acute gonococcal upper reproductive tract infection classically are menstruating or have just completed their menses. Last, treatment with broad-spectrum antibiotics may result in symptoms attributed to inflammation from *Candida albicans* or other *Candida* species by eradicating other balancing species in the flora.

Bacterial Vaginosis (BV)

This common, complex, and poorly understood clinical syndrome reflects vaginal flora in which anaerobic species are overrepresented. These include *Gardnerella*, *Prevotella*, *Mobiluncus*, and *Bacteroides* species; *Atopobium vaginae*; and BV-associated bacteria, provisionally named BVAB1, BVAB2, and BVAB3. These latter three are newly recognized bacteria found in women with BV (Fredricks, 2005). BV is also associated with a significant reduction of normal *Lactobacillus* species.

Molecular ribosomal RNA gene sequencing techniques have greatly aided classification of specific bacteria within vaginal flora ecosystems, which are also called *vaginal microbiota* or *vaginal biomes*. There are five types of vaginal microbiota, referred to as *community state types (CSTs)*. CSTs are defined by their specific clustering of specific species. And, a woman can be categorized to one of these five CSTs based on her vaginal microbiota composition (Ravel, 2011). Researchers have begun to quantify the

risk of BV by these CST groups. Specifically, CSTs I, II, III, and V are lactobacilli rich. In contrast, CST IV is a heterogeneous microbiota of strict anaerobes and is associated with BV. CSTs vary racially, and CST IV is also the most common in asymptomatic, healthy black women (Fettweis, 2014).

In evaluating risks for BV, this condition is not considered by the Centers for Disease Control and Prevention (CDC) (2015) to be a sexually transmitted disease (STD). However, a greater risk of BV is associated with multiple or new sexual partners, female partners, and oral sex, whereas condom use lowers the risk (Fethers, 2008). Moreover, rates of STD acquisition are increased in affected women, and a possible role of sexual transmission in the pathogenesis of recurrent BV has been proposed (Atashili, 2008; Bradshaw, 2006; Wiesenfeld, 2003). Other potential risks are douching, black race, smoking, and intrauterine device (IUD) use.

BV is the most common cause of vaginal discharge among reproductive-aged women. Of symptoms, a nonirritating, malodorous vaginal discharge is characteristic but may not always be present. The vagina is usually not erythematous, and cervical examination reveals no abnormalities.

For diagnosis, clinical criteria first proposed by Amsel and associates (1983) include: (1) microscopic evaluation of a vaginal-secretion saline preparation, (2) release of volatile amines produced by anaerobic metabolism, and (3) determination of the vaginal pH. A saline preparation, also known as a "wet prep," contains a swab-collected sample of discharge mixed with drops of saline on a microscope slide. Clue cells are the most reliable indicators of BV and were originally described by Gardner and Dukes (1955) (Fig. 3-1). These vaginal epithelial cells contain many attached bacteria, which create a poorly defined stippled cellular border. At least 20 percent of the epithelial cells should be clue cells. The positive predictive value of this test for BV is 95 percent.

Adding 10-percent potassium hydroxide (KOH) to a fresh sample of vaginal secretions releases volatile amines that have a fishy odor. This is often colloquially referred to as a "whiff test." The odor is frequently evident even without KOH. Similarly, alkalinity of seminal fluid and blood are responsible for foul-odor complaints after intercourse and with menses. The finding of both clue cells and a positive whiff test result is pathognomonic, even in asymptomatic patients.

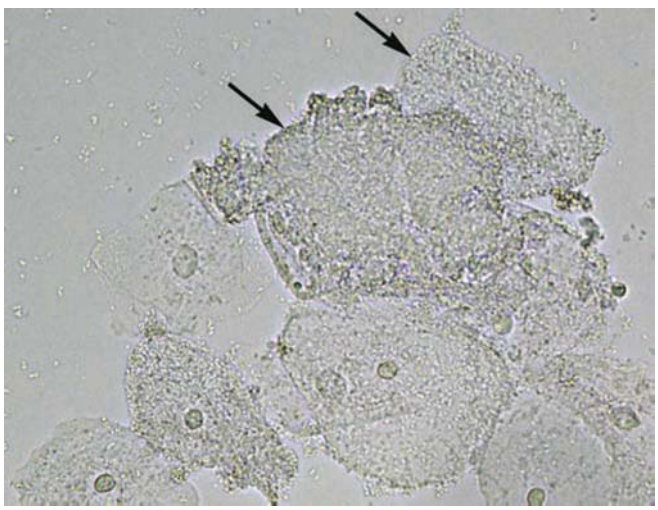

FIGURE 3-1 Photomicrograph of saline wet preparation reveals clue cells. Several of these squamous cells are heavily studded with bacteria. Clue cells are covered to the extent that cell borders are blurred and nuclei are not visible (*arrows*). (Reproduced with permission from Dr. Lauri Campagna and Mercedes Pineda, WHNP.)

Characteristically with BV, the vaginal pH is >4.5, and this stems from diminished acid production by bacteria. Similarly, *Trichomonas vaginalis* infection also is associated with anaerobic overgrowth and elaboration of amines. Thus, women diagnosed with BV should have no microscopic evidence of trichomoniasis.

Used primarily in research studies rather than clinical practice, the Nugent Score is a system employed for diagnosing BV. During microscopic examination of a gram-stained vaginal discharge smear, scores are calculated by assessing bacteria staining and morphology.

Last, molecular DNA assays against the more frequent organisms found in women with BV have suitable accuracy (Coleman, 2018). However, these tests assess for bacteria that may also be part of normal flora in asymptomatic women. Moreover, compared with traditional methods, molecular tests have yet to show superior health outcomes but do add substantial cost.

Several gynecologic adverse health outcomes have been observed in women with BV. These include vaginitis, endometritis, postabortal endometritis, pelvic inflammatory disease (PID) unassociated with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*, susceptibility to human immunodeficiency virus (HIV) acquisition, and acute pelvic infections following pelvic surgery, especially hysterectomy (Atashili, 2008; Larsson, 1989, 1991, 1992; Soper, 1990). Pregnant patients with BV have an elevated risk of preterm delivery and postpartum endometritis (Hillier, 1995; Watts, 1990).

Several regimens are available for nonpregnant women (Table 3-1). The newest of these is secnidazole, a 5-nitroimidazole in granule form taken once orally (Schwebke, 2017). Cure rates with regimens in Table 3-1 range from 80 to 90 percent at 1 week, but within 3 months, 30 percent of women have experienced a recurrence. Many of these are correlated with heterosexual contact (Amsel, 1983; Gardner, 1955; Wilson, 2004). However, treatment of male sexual partners does not benefit women with this recurring condition and is not recommended. Moreover, other forms of therapy such as introduction of lactobacilli, acidifying vaginal gels, and use of probiotics have shown inconsistent efficacy (Senok, 2009).

Limited evidence supports specific ways to prevent BV. Alteration of previously mentioned risk factor behaviors can be considered. Of these, some data suggest elimination or diminished use of vaginal douches may have benefits (Brotman, 2008; Klebanoff, 2010).

GENITAL ULCER INFECTIONS

Ulceration defines complete loss of the epidermal covering with invasion into the underlying dermis. In contrast, *erosion* describes partial loss of the epidermis without dermal penetration. These are distinguished by clinical examination. Biopsies are generally not helpful. But if taken, samples obtained from the edge of new lesions are the most likely to be informative.

TABLE 3-1. Single-Agent Bacterial Vaginosis Treatment

Recommended regimens	
Metronidazole (Flagyl)	500 mg orally twice daily for 7 days
Metronidazole gel 0.75% (Metrogel vaginal)	5 g (1 full applicator) intravaginally once daily for 5 days
Clindamycin cream[a] 2% (Cleocin, Clindesse)	5 g (1 full applicator) intravaginally at bedtime for 7 days
Alternative regimens	
Secnidazole (Solosec)	2 g orally once[b]
Tinidazole (Tindamax)	2 g orally once daily for 2 days
	1 g orally once daily for 5 days
Clindamycin	300 mg orally twice daily for 7 days
Clindamycin ovules[a] (Cleocin)	100 mg intravaginally at bedtime for 3 days

[a]Clindamycin cream and ovules are oil-based and might weaken latex condoms and diaphragms for 5 days after use.
[b]These granules are mixed with applesauce, yogurt, or pudding and are not chewed.
From the Centers for Disease Control and Prevention, 2015; Schwebke, 2017.

Importantly, biopsy is mandatory if carcinoma is suspected, and Figure 4-2 (p. 94) illustrates technique.

Most young sexually active women in the United States who have genital ulcers will have herpes simplex virus (HSV) infection or syphilis. Rarely, some will have chancroid, lymphogranuloma venereum, or granuloma inguinale. Essentially all are sexually transmitted and are associated with higher risk for HIV transmission.

As a general rule, females diagnosed with one STD are offered testing for others. This typically includes testing for syphilis, gonorrhea, and HIV, chlamydial, and hepatitis B infections. Sexual contacts require evaluation, and both require reassessment following treatment.

Herpes Simplex Virus Infection

Genital herpes is the most prevalent genital ulcer disease and is a chronic viral infection. After crossing an epithelial barrier, the virus enters sensory nerve endings and undergoes retrograde axonal transport to the dorsal root ganglion. Here, the virus develops lifelong latency. Spontaneous reactivation by various events results in anterograde transport of virus to the surface. The virus is shed, with or without lesion formation. It is postulated that immune mechanisms control latency and reactivation.

There are two types of herpes simplex virus, HSV-1 and HSV-2. HSV-1 is the predominant cause of oral lesions and often is acquired in childhood. Additionally, HSV-1 is now the most frequent agent of genital lesions in Hispanic and white women (Bernstein, 2013). This rise in the prevalence of HSV-1 genital disease may stem from an increase in oral–genital sexual practices. Another explanation is that HSV-1 acquisition has declined in childhood as a result of improved living conditions and hygiene. Without prior exposure, this renders people without HSV-1 antibodies susceptible to genital acquisition of HSV-1 or -2. HSV-2 causes primarily genital lesions and is the most common source of genital disease in black women (Fanfair, 2013). Of all females aged 14 to 49 years in the United States, 16 percent have suffered a genital HSV-2 infection, and nearly 55 percent are seropositive to HSV-1 (Bradley, 2014).

Most women who have been infected with either HSV-1 or HSV-2 lack a formal diagnosis because of mild or unrecognized infections. Infected patients can shed infectious virus while asymptomatic, and most infections are transmitted sexually by patients who are unaware of their infection. Compared with men, women have more severe symptoms with primary and recurrent infection.

Symptoms

Patient symptoms at initial presentation will depend primarily on whether a patient during the current episode has antibody from previous exposure. If a patient has no antibody, the attack rate in an exposed person approaches 70 percent. The mean incubation period is approximately 1 week. Up to 90 percent of those who are symptomatic with their initial infection will have another episode within a year.

The virus infects viable epidermal cells, the response to which is erythema and papule formation. With cell death and cell wall lysis, blisters form (Fig. 3-2). The covering then disrupts, leaving a usually painful ulcer. These lesions develop crusting and heal but may become secondarily infected. The three stages of lesions are: (1) vesicle with or without pustule formation, which lasts approximately a week; (2) ulceration; and (3) crusting. Virus is predictably shed during the first two phases.

Burning and severe pain accompany initial vesicular lesions. With ulcers, urinary frequency and/or dysuria from direct contact of urine with ulcers may be complaints. Rarely, local swelling can result from vulvar lesions and cause urethral obstruction. Alternatively or additionally, herpetic lesions can involve the vagina, cervix, bladder, anus, and rectum. Commonly, low-grade fever, headache, and myalgias are noted.

Viral load undoubtedly contributes to the number, size, and distribution of lesions. Normal host defense mechanisms inhibit viral growth, and healing starts within 1 to 2 days. Early treatment with an antiviral medication decreases the viral load. Immune-deficient patients have greater susceptibility and display diminished immune response and delayed healing.

For a previously uninfected patient, the period of new lesion formation and time to healing are both longer. Pain persists for

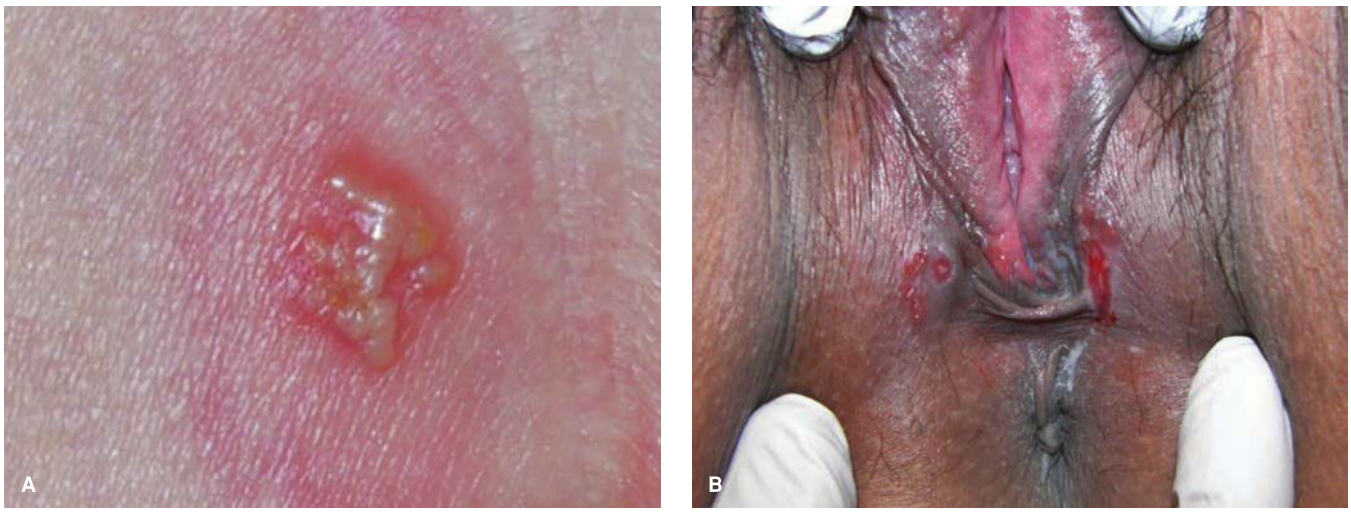

FIGURE 3-2 Genital herpetic ulcers. **A.** Vesicles prior to ulceration. **B.** Punctate (*left*) or "knife-cut" (*right*) ulcers are common lesions. (Reproduced with permission from Dr. William Griffith.)

the first 7 to 10 days, and lesions heal by 2 to 3 weeks. If a patient has had prior exposure to HSV-2, their initial episode is significantly less severe, and time to healing approximates 2 weeks.

Recurrence following HSV-2 infection is common, and almost two thirds of patients have a prodrome prior to lesion onset. Heralding paresthesias are frequently described as pruritus or tingling in the area prior to vesicle formation. However, prodromal symptoms may develop without actual lesion formation. Clinical manifestations for women with recurrences are more limited, with only approximately 1 week of symptoms.

Diagnosis

The gold standard for diagnosing genital herpes was previously cell culture. Specificity is high, but sensitivity is low and declines as lesions heal. Nucleic acid amplification test (NAAT) testing is many times more sensitive than culture and can detect HSV DNA shed from epithelia without vesicular lesions (LeFoff, 2014). Moreover, results generally are available in 1 to 2 days. Importantly, a negative culture or polymerase chain reaction (PCR) result does not mean that there is no herpetic infection. In contrast, false-positive results are rare.

HSV is surrounded by envelope glycoproteins, and glycoprotein G is the antigen of interest. Serologic assays are available to detect antibodies formed against the HSV type-specific glycoproteins, namely glycoprotein G2 (HSV-2) or glycoprotein G1 (HSV-1). Assay specificity is ≥96 percent, and the sensitivity of HSV-2 antibody testing ranges from 80 to 98 percent. Importantly, with serologic screening, only immunoglobulin G (IgG) antibody assays are ordered. Although these tests may be used to confirm herpes simplex infection, seroconversion following initial infection takes approximately 3 weeks (Ashley-Morrow, 2003). Immunoglobulin M (IgM) testing is not recommended. This can lead to ambiguous results as the IgM assays are not type-specific and also may be positive during a recurrent outbreak. Thus, in clinically obvious cases, immediate treatment and additional STD screening can be initiated following physical examination alone.

Serologic screening for HSV in the asymptomatic general population is not recommended. However, HSV serologic testing can be considered for HIV-infected individuals or for women presenting for an STD evaluation, especially for those with multiple partners and for those in demographics with high prevalence (Fanfair, 2013). It can also add management information for couples thought but not confirmed to be discordant for infection (Centers for Disease Control and Prevention, 2015).

Treatment

The CDC provides and regularly updates guidelines for the treatment of all STDs. These are found on the CDC website at: www.cdc.gov/std/tg2015/default.htm. For HSV, currently available antiviral therapy is listed in Table 3-2. Although these agents may hasten healing and improve symptoms, therapy does not eradicate latent virus or affect future rates of recurrent infection. Analgesia with nonsteroidal antiinflammatory drugs or, if severe, a mild narcotic such as acetaminophen with codeine may be prescribed. In addition, topical anesthetics such as lidocaine ointment may provide relief. Local hygiene to prevent secondary bacterial infection is important.

For women with established HSV-2 infection, therapy may not be necessary if symptoms are mild and tolerable. Episodic therapy for recurrent disease is ideally initiated at least within 1 day of lesion outbreak or during the prodrome. Patients may be given a prescription ahead of time so that medication is available to begin therapy with prodrome onset.

If episodes recur at frequent intervals, a woman may elect daily suppressive therapy, which reduces recurrences by 70 to 80 percent (Centers for Disease Control and Prevention, 2015). Suppressive therapy may eliminate recurrences and decreases sexual transmission. Once-daily dosing may result in enhanced compliance and lower cost.

Patient education is mandatory, and specific topics include prodrome recognition, recurrence triggers, methods to reduce sexual transmission, and obstetric consequences. Acquisition of this infection may have significant psychological impact, and several websites provide patient information and support. A useful CDC website is www.cdc.gov/std/Herpes/STDFact-Herpes.htm.

TABLE 3-2. Oral Agents for Genital Herpes Simplex Infection

First clinical episode
Acyclovir 400 mg three times daily for 7–10 days
or
Acyclovir 200 mg five times daily for 7–10 days
or
Famciclovir (Famvir) 250 mg three times daily for 7–10 days
or
Valacyclovir (Valtrex) 1 g twice daily for 7–10 days

Episodic therapy for recurrent disease
Acyclovir 400 mg three times daily for 5 days
or
Acyclovir 800 mg twice daily for 5 days
or
Acyclovir 800 mg three times daily for 2 days
or
Famciclovir 125 mg twice daily for 5 days
or
Famciclovir 1 g twice daily for 1 day
or
Famciclovir 500 mg once, then 250 mg twice daily for 2 days
or
Valacyclovir 500 mg twice daily for 3 days
or
Valacyclovir 1 g once daily for 5 days

Suppressive therapy
Acyclovir 400 mg twice daily
or
Famciclovir 250 mg twice daily
or
Valacyclovir 0.5 or 1 g once daily

From the Centers for Disease Control and Prevention, 2015.

Prevention

Women with genital herpes should refrain from sexual activity with uninfected partners when prodrome symptoms or lesions are present. Latex condom use potentially lowers the risk for herpetic transmission (Martin, 2009). Suppressive therapy with oral valacyclovir 0.5 g daily reduces sexual transmission by almost 50 percent among couples discordant for HSV-2 (Corey, 2004). Unfortunately, preventive herpes vaccine trials have failed to demonstrate protective immunity in the genital tract (Belshe, 2012; Shin, 2013).

Syphilis

Pathophysiology

Syphilis is an STD caused by the spirochete *Treponema pallidum*, which is a slender, spiral-shaped organism with tapered ends. Women at highest risk are those from lower socioeconomic groups, adolescents, those with early onset of sexual activity, and those with many sexual partners. The number of syphilis cases has risen almost every year in the United States since 2001. In 2017, more than 100,000 cases of syphilis, which included all stages, were reported to the CDC (2018a).

FIGURE 3-3 Several vulvar syphilitic chancres. Lesions that lie directly across the vulvar midline from each other are sometimes referred to as "kissing" lesions.

The natural history of syphilis in untreated patients can be divided into four stages. Of these, primary and secondary syphilis represent incident infection. With primary syphilis, the hallmark lesion is the *chancre*, in which spirochetes are abundant. Classically, it is an isolated, nontender ulcer with raised, rounded borders and an uninfected base (Fig. 3-3). However, it may become secondarily infected and painful. Chancres are often found on the cervix, vagina, or vulva but may also form in the mouth or around the anus. The mean incubation period is 3 weeks, but lesions can develop 10 days to 3 months after exposure. Without treatment, lesions spontaneously heal within 6 weeks.

With *secondary syphilis,* bacteremia develops 6 weeks to 6 months after a chancre appears. Its hallmark is a maculopapular rash that may involve the entire body and includes the palms, soles, and mucous membranes (Fig. 3-4). Mucosal lesions, called *mucous patches*, actively shed spirochetes. In warm, moist body areas, this rash may produce broad, pink or gray-white, highly infectious plaques called *condylomata lata*. Because syphilis is a systemic infection, other manifestations may include fever and malaise. Less commonly, cranial nerve dysfunction, meningitis, hepatitis, nephrotic syndrome, and arthritis develop.

Untreated, the manifestations of secondary syphilis resolve, and latent syphilis is diagnosed using serologic tests. During *early latent syphilis*, which is diagnosed within 1 year of infection, secondary signs and symptoms may recur. *Late latent syphilis* is defined as a period greater than 1 year after the initial infection.

Tertiary syphilis is the phase of untreated syphilis that may appear up to 20 years after latency. During this phase, cardiovascular, central nervous system, and musculoskeletal involvement become apparent. However, cardiovascular and neurosyphilis are half as common in females as in males.

Diagnosis

A definitive diagnosis requires direct detection of spirochetes within a lesion sample. However, most cases are diagnosed presumptively

FIGURE 3-4 Secondary syphilis. **A.** Woman with multiple condyloma lata on her labia. Soft, flat, moist, pink-tan papules and nodules on the perineum and perianal area are typical. (Reproduced with permission from Dr. George Wendel.) **B.** Woman with multiple keratotic papules on her palms. With secondary syphilis, disseminated papulosquamous eruptions may be seen on the palms, soles, or trunk. (Reproduced with permission from Dr. Devin Macias.) **C.** Characteristic rash on this woman's torso. (Reproduced with permission from Dr. Eddie McCord.)

using clinical assessment plus serologic testing. Serologic testing includes both nontreponemal and treponemal-specific tests. The two nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests. Both tests measure patient IgM and IgG antibodies formed against cardiolipin that is released from damaged host cells and possibly also from treponemes. Notably, these same antibodies can also be produced in response to recent vaccination, febrile illness, pregnancy, or chronic conditions such as intravenous (IV) drug abuse, systemic lupus erythematosus, aging, or cancer. These all serve as potential sources of false-positive results (Larsen, 1995). With true infection, seroconversion occurs at approximately 3 weeks but can take up to 6 weeks (Peeling, 2004). Thus, women with very early primary syphilis can have initially false-negative serologic test results.

With positive nontreponemal test results, findings are quantified and expressed as titers. In the traditional screening algorithm, a positive nontreponemal test result in a woman who has not been treated previously for syphilis will prompt clinical assessment and confirmation with a treponemal-specific test. These are either the fluorescent treponemal antibody-absorption (FTA-ABS) or *Treponema pallidum* particle agglutination (TP-PA). These species-specific tests remain positive for life following infection. If the treponemal-specific test results also are positive, treatment is then provided. In a woman previously treated for syphilis, a fourfold (two dilution) rise in nontreponemal titer suggests reinfection, and retreatment is provided.

In an alternative "reverse" screening algorithm, a treponemal-specific enzyme or chemiluminescence immunoassay (EIA or CIA) is used first. If positive results are found, RPR or VDRL testing is then performed along with clinical assessment to determine timing of infection (Table 3-3). In this scenario, a positive screening EIA or CIA result reflects either *current* or

TABLE 3-3. Interpretation of Serologic Tests Using Reverse Sequence Syphilis Screening

Treponemal Test	VDRL or RPR	TP-PA	Possible Interpretations
Nonreactive	Nonreactive[a]		1. Absence of syphilis 2. Very early syphilis before seroconversion
Reactive[b]	Nonreactive Reactive Nonreactive	Reactive Reactive Nonreactive	1. Prior treated syphilis 2. Untreated syphilis 3. False-positive treponemal test[c]
Reactive	Reactive		1. Active syphilis 2. Recently treated syphilis with nontreponemal titers that have not yet become nonreactive 3. Treated syphilis with persistent titers[d]
Nonreactive	Reactive[a]		1. False-positive nontreponemal test

[a]Usually not performed if the initial treponemal test is negative.
[b]By 2 different methods if the nontreponemal test is nonreactive.
[c]May be seen in pregnancy or among immigrants with previous exposure to endemic treponematoses.
[d]Successful treatment is usually considered with a fourfold decline in titers (e.g., from 1:32 to 1:8).
RPR = rapid plasma reagin; TP-PA = *Treponema pallidum* particle agglutination; VDRL = Venereal Disease Research Laboratory.
Derived from Centers for Disease Control and Prevention, 2011.

past infection because treponemal-specific antibodies typically remain positive for life. For patients with discordant screening results (EIA/CIA+ and RPR/VDRL-), TP-PA is performed. If the TP-PA result is positive and documentation of prior syphilis treatment is lacking, antibiotics are then administered. Management of patients using the reverse algorithm relies heavily on disease history and physical findings.

Following treatment of patients diagnosed using either the traditional or reverse algorithm, sequential nontreponemal tests are performed. During this surveillance, the same type of test—either RPR or VDRL-is ideally used for consistency. A fourfold titer decline is expected by 6 to 12 months after therapy for primary or secondary syphilis. Patients with latent syphilis or initially low nontreponemal antibody titers are less likely to achieve a fourfold drop. Although nontreponemal tests usually become nonreactive after treatment, some women may have persistently low titer results. These patients are described as *serofast*.

Treatment

Penicillin is the first-line therapeutic agent for this infection, and benzathine penicillin is primarily chosen. Specific recommendations for therapy by the CDC (2015) are listed in Table 3-4. Within the first 24 hours after treatment of early disease, an acute, self-limited febrile response, termed a *Jarisch-Herxheimer reaction*, may develop and is associated with headache and myalgia.

Up to 10 percent of the general population may manifest an allergic reaction to penicillins. The lowest risk is associated with oral preparations, whereas the highest follows those combined with procaine and given intramuscularly (IM). For patients with penicillin allergy who cannot be surveilled posttherapy or whose compliance is questioned, skin testing, desensitization, and treatment with IM benzathine penicillin is recommended (Wendel, 1985). Desensitization can be performed relatively safely and outlined at the CDC website: www.cdc.gov/std/tg2015/pen-allergy.htm.

After initial treatment, women are seen at 6-month intervals for clinical evaluation and serologic retesting. If the expected fourfold titer decline does not occur, possible reinfection or treatment failure is considered. Retreatment recommendation is benzathine penicillin G, 2.4 million units IM weekly for 3 weeks.

TABLE 3-4. Treatment of Syphilis

Primary, secondary, early latent (<1 year) syphilis
Recommended regimen:
Benzathine penicillin G, 2.4 million units IM once
Alternative oral regimens (penicillin-allergic, nonpregnant women): Doxycycline 100 mg orally twice daily for 2 weeks
Late latent, tertiary, and cardiovascular syphilis
Recommended regimen:
Benzathine penicillin G, 2.4 million units IM weekly times 3 doses
Alternative oral regimen (penicillin-allergic, nonpregnant women): Doxycycline 100 mg orally twice daily for 4 weeks

From the Centers for Disease Control and Prevention, 2015.

Chancroid

Chancroid, granuloma inguinale, and lymphogranuloma venereum are each rare STDs in the United States. Thus, any evaluation of genital ulcer disease first includes testing to exclude syphilis and HSV infection, which are much more common.

Chancroid is caused by *Haemophilus ducreyi*, and following exposure, incubation usually spans 3 to 10 days. One or more erythematous papules then become pustular and ulcerate. These painful genital ulcers classically have soft irregular margins and friable bases. In addition, many patients develop tender inguinal lymphadenopathy. If large and fluctuant, these *buboes* may suppurate and form fistulas.

Previously, definitive diagnosis required growth of *H ducreyi* in cell culture, but now the accepted standard for diagnosis is a NAAT (Romero, 2017). No *H ducreyi* PCR is Food and Drug Administration (FDA)-cleared in the United States (Copeland, 2016). A presumptive diagnosis can be made from a Gram stain of lesion contents that show small gram-negative rods in a chain. Superficial debris is ideally first removed.

For treatment, the CDC's (2015) recommended regimens include either a single dose of oral azithromycin (1 g) or of IM ceftriaxone (250 mg). Second-line, multidose options are ciprofloxacin or erythromycin base.

Granuloma Inguinale

Also known as donovanosis, granuloma inguinale is caused by the gram-negative bacterium *Klebsiella granulomatis*. Incubation may last from days to weeks, and infection presents with painless inflammatory nodules that progress to highly vascular, nontender ulcers. These ulcers heal by fibrosis, which can result in scarring resembling keloids. Lymph nodes are usually uninvolved.

Culturing this organism is difficult, and FDA-approved PCR tests for *K granulomatis* are lacking (Copeland, 2016). Instead, diagnosis is confirmed by identification of Donovan bodies, which appear as a "closed safety pin" during microscopic cytologic evaluation following Wright-Giemsa staining.

Treatment recommended by the CDC (2015) is azithromycin 1 g once weekly for at least 3 weeks and until lesions are completely healed. Alternative regimens include doxycycline, ciprofloxacin, trimethoprim-sulfamethoxazole, or erythromycin base. Improvement will be evident within the first few treatment days, but resolution may be lengthy and relapses have been reported.

Lymphogranuloma Venereum

This ulcerative genital disease is caused by *C trachomatis* serotypes L1, L2, and L3. Although uncommon in the United States, rates have risen in men having sex with men (Stoner, 2015). Incubation ranges from 3 days to 2 weeks, and lymphogranuloma venereum (LGV) is divided into three stages: (1) small painless papule, (2) regional lymphadenopathy, and (3) anogenitorectal

fibrosis (Ceovic, 2015). In the primary stage, initial papules heal quickly and without scarring. During the second stage, inguinal and femoral lymph nodes progressively enlarge. Painful nodes can mat together on either side of the inguinal ligament to create a "groove sign." Nodes may then rupture and lead to chronically draining sinuses. Malaise, fever, and arthralgias also can be comorbid. In the third stage, tissue destruction and scarring are prominent, and sequela of lymphatic obstruction can develop.

LGV may be diagnosed by positive chlamydial testing. Specifically, culture or immunofluorescence or NAAT testing of samples from genital lesions, affected lymph nodes, or rectum are suitable. Moreover, a chlamydial serologic titer that is >1:64 can support the diagnosis. For treatment, the CDC (2015) recommends doxycycline, 100 mg orally twice daily for 21 days. An alternative is erythromycin base.

INFECTIOUS VAGINITIS

Symptomatic vaginal discharge most often reflects BV, candidiasis, or trichomoniasis. *Aerobic vaginitis* is a newly described disturbance of vaginal microbiota that leads to inflammation and discharge. Microscopic discharge evaluation shows increased white blood cell (WBC) counts, a greater number or aerobic species, but diminished lactobacilli counts (Sherrard, 2018). This is described further in Chapter 4 (p. 107).

BV typically evokes complaints of foul discharge odor without irritation. In contrast, if abnormal discharge is associated with vulvar burning, irritation, or itching, then *vaginitis* is diagnosed. Between 7 and 70 percent of women who have vaginal discharge complaints will have no definitive diagnosis (Anderson, 2004). For those in whom identifiable infection is absent, an inflammatory diagnosis and treatment for infection should not be given. In such instances, a woman may seek reassurance, having concern about a recent sexual exposure, and STD screening may alleviate this.

Initial Evaluation

During initial steps, a provider obtains information regarding prior vaginal infections and their treatment, symptom duration, specifics of self-treatment with over-the-counter (OTC) preparations, and a complete menstrual and sexual history. The salient features of a menstrual history are outlined in Chapter 8 (p. 182). A sexual history typically includes questions regarding age at coitarche, date of most recent sexual activity, number of recent partners, gender of those partners, use of condom protection, method of birth control, prior STD history, and type of sexual practices—anal, oral, or vaginal.

A thorough physical examination of the vulva, vagina, and cervix also is performed. Several etiologies may be identified in the office by microscopic examination of the discharge (Table 3-5). First, a saline preparation, described earlier, can be inspected (p. 57). A "KOH-prep" contains a swab-collected sample of discharge mixed with several drops of 10-percent potassium hydroxide. KOH leads to osmotic swelling and then lysis of squamous cell membranes. This visually clears the microscopic view and aids identification of fungal buds or hyphae, whose cell walls remain intact. Finally, vaginal pH analysis may add supportive information. Vaginal pH can be estimated using chemical testing paper strips. Appropriate readings are obtained by pressing a test strip directly to the upper vaginal wall and resting it there for a few seconds to absorb vaginal fluid. Once the strip is removed, its color is matched to the color indicator chart on the test strip dispenser. Importantly, blood and semen are alkaline and often will artificially elevate pH. Unfortunately, inexpensive laboratory tests such as these are not as accurate as a clinician would hope (Landers, 2004; Lowe, 2009).

A laboratory PCR panel specific for candidal species, *T vaginalis*, and BV species is now available (Gaydos, 2017a). This FDA market-authorized panel shows greater sensitivity than the clinical tests described in the prior paragraphs (Schwebke, 2018). However, in addition to added cost, it is unclear which

TABLE 3-5. Characteristics of Some Vaginal Infections

Category	Complaint	Discharge	KOH "Whiff Test"	Vaginal pH	Microscopic Findings
Normal	None	White, clear	–	3.8–4.2	NA
BV	Odor, increased after intercourse and/or menses	Thin, gray or white, adherent, often increased	+	>4.5	Clue cells, bacteria clumps (saline wet prep)
Candidiasis	Itching, burning, discharge	White, curdy	–	<4.5	Hyphae and buds (10-percent KOH solution wet prep)
Trichomoniasis	Frothy discharge, odor, dysuria, pruritus, spotting	Green-yellow, frothy, adherent, increased	±	>4.5	Motile trichomonads (saline wet prep)
Aerobic vaginitis[a]	Thin, watery discharge, pruritus	Purulent	–	>4.5	Many WBCs

[a]*Escherichia coli* or streptococcal or staphylococcal species.
BV = bacterial vaginosis; KOH = potassium hydroxide; NA = not applicable; WBC = white blood cell.

women may benefit because many cases of vaginitis can be diagnosed solely by clinical means.

Fungal Infection

C albicans can be found in the vagina of asymptomatic patients and is a commensal of the mouth, rectum, and vagina. However, imbalance between this yeast and its host can develop and can lead to vulvovaginal candidiasis. Occasionally, other *Candida* species may be involved and include *C tropicalis* and *C glabrata,* among others. Candidiasis is seen more often in patients with immunosuppression, diabetes mellitus, pregnancy, and recent broad-spectrum antibiotic use (Nyirjesy, 2013). Sexual transmission is uncommon, and treatment of sexual partners is unnecessary.

With candidiasis, vulvar pruritus, burning, erythema, and edema with excoriations are common (Fig. 3-5). The typical vaginal discharge is described as curdy or cottage cheese–like. Microscopic examination of vaginal discharge with saline and with 10-percent KOH preparations allows yeast identification. *C albicans* is dimorphic, with both yeast buds and hyphal forms. It may be present in the vagina as a filamentous fungus (pseudohyphae) or as germinated yeast with mycelia. Vaginal candidal culture is not routinely recommended. However, it may be indicated for those who fail empiric treatment and for women with evidence of infection yet absence of microscopic yeast.

The CDC classifies vulvovaginal candidiasis (2015) into "uncomplicated" and "complicated." Uncomplicated cases are sporadic or infrequent, are mild to moderate in symptom severity, are likely caused by *C albicans*, and involve immunocompetent women. For both uncomplicated and complicated infection, effective treatment formulations are listed in Table 3-6. Conceptually, the vagina can be considered a reservoir for which treatment lowers the infectious load, whereas the vulva is more often the site of symptoms (Donders, 2017). Thus, several of the listed products are combination packs that contain separate treatments for both vagina and vulva. For uncomplicated infection, azoles are extremely effective, and women require specific follow-up only if therapy is unsuccessful.

However, 10 to 20 percent of women have complicated candidiasis. This term encompasses infections with frequent recurrence or greater symptom severity, those from non-*albicans* species, or those in immunosuppressed patients. For women with complicated infection, cultures are obtained to direct care, and longer therapy may be needed to achieve clinical cure. Examples include local intravaginal therapy for 7 to 14 days.

By definition, *recurrent disease* reflects four or more candidal infections during a year. For recurrent *C albicans* disease, local intravaginal therapy for 7 to 14 days is an option. Alternatively, oral fluconazole (Diflucan) in 100-mg, 150-mg, or 200-mg strengths once every third day for a total of three doses (day 1, 4, and 7) may be chosen. Suppressive maintenance for recurrence prevention is with oral fluconazole, 100 to 200 mg weekly for 6 months. Non-*albicans* candidal species are less responsive to topical azole therapy. For non-*albicans* recurrent infection, a 600-mg boric acid gelatin capsule intravaginally at bedtime for 2 weeks may be successful. Prefilled capsules can be purchased OTC or can be assembled personally by filling a 0-size gelatin capsule with boric acid powder.

Oral azole therapy has been associated with serum liver enzyme elevation. Additionally, interactions with multiple medications that include certain antacid, antihypertensive, antiseizure, antiretroviral, immunosuppressive, and antilipidemic drugs have been reported (Brüggemann, 2009). In cases in which prolonged oral therapy is not feasible due to potential interactions, local intravaginal therapy once or twice weekly may give a similar clinical response.

Last, probiotics have been suggested as treatment or adjuncts to traditional therapy. However, evidence to support either role is not robust (Xie, 2017). Moreover, agreement on the preferred bacterial species is lacking.

Trichomoniasis

This infection is the most prevalent nonviral STD worldwide (Newman, 2015). And, in one large U.S. national survey, the prevalence was 1.8 percent in women aged 18 to 59 (Patel, 2018).

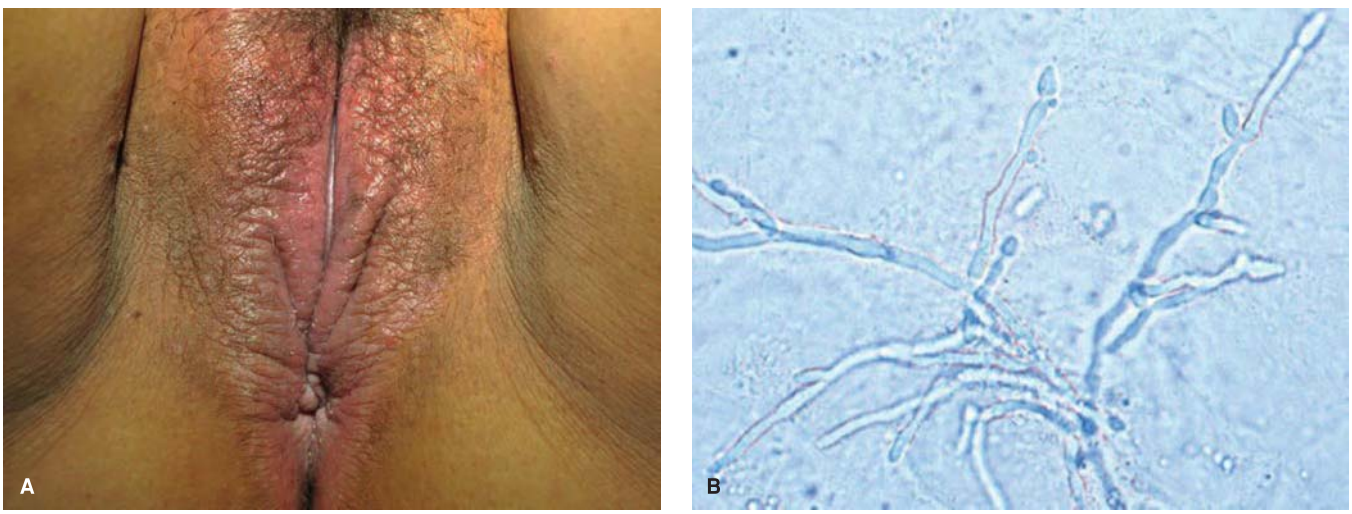

FIGURE 3-5 Candidal infection. **A.** Mild erythema and edema of the affected vulva creates a slightly leathery skin texture. [c]Maximum use recommended is 2 weeks.
app = applicatorful; supp = suppository.

Unlike other STDs, its incidence appears to increase with patient age (Stemmer, 2018). Most men are asymptomatic, but up to 70 percent of male partners of women with vaginal trichomoniasis will have trichomonads in their urinary tract (Seña, 2007).

Diagnosis

Incubation with *T vaginalis* requires 3 days to 4 weeks, and the vagina, urethra, endocervix, and bladder can be infected. No symptoms are noted in up to one half of women with trichomoniasis, and such colonization can persist for months or years. Notably, trichomoniasis is associated with a nearly twofold greater risk for HIV acquisition (McClelland, 2007; Laga, 1993). In those with complaints, vaginal discharge is typically described as foul, thin, and yellow or green. Dysuria, dyspareunia, vulvar pruritus, vaginal spotting, and lower abdominal pain also may be noted.

Of clinical findings, the vagina contains the discharge just described, and subepithelial hemorrhages or "strawberry spots" dot the vagina and cervix. Vaginal pH is often elevated. Microscopically, WBC numbers are increased in saline preparations of the discharge. Trichomonads are oval anaerobic protozoa that are slightly larger than a WBC and have anterior flagella (Fig. 3-6). Microscopic identification of these motile parasites is diagnostic. However, trichomonads are less motile with cooling, and slides ideally are examined within 10 to 30 minutes (Kingston, 2003; Stoner, 2013). Inspection of a saline preparation is highly specific, yet its sensitivity ranges from 40 to 70 percent (Nathan, 2015; Nye, 2009; Schwebke, 2018).

Laboratory-based NAATs for trichomonal DNA are the most sensitive and specific tests (Meites, 2015). Suitable specimens include endocervical swab, vaginal swab, or urine. However, NAAT testing adds cost, and results are not immediately available. Alternatively, point-of-care in-clinic testing is possible but again adds cost and is not recommended for asymptomatic patients. Of these, the OSOM Trichomonas Rapid Test is an immunochromatographic assay that provides results in 10 minutes. It offers 88-percent sensitivity and 99-percent specificity (Huppert, 2005, 2007). With similar accuracy, the Solana Trichomonas Assay uses a DNA hybridization probe and yields results within 1 hour (Gaydos, 2017b). Although these molecular tests may add accuracy compared with microscopy, diagnostic test selection ideally factors patient risks and symptoms, laboratory capabilities, and cost.

Culture and antimicrobial susceptibility analysis play a lesser diagnostic role and are elected mainly in cases of persistent infection or suspected treatment failure. For culture, the commercially available InPouch system provides suitable sensitivity, 100-percent specificity, and results within 3 days (Hobbs, 2013). Diamond's media for culture is less widely available and requires 7 days. Last, trichomonads can also be noted on Pap screening slides and diagnostic sensitivity approximates 60 percent (Wiese, 2000). If trichomonads are reported from a Pap test, confirmation by microscopic evaluation of a saline preparation is encouraged prior to treatment (American College of Obstetricians and Gynecologists, 2017b).

Treatment

Oral regimens recommended by the CDC (2015) are either metronidazole 2 g once or tinidazole (Tindamax) 2 g once.

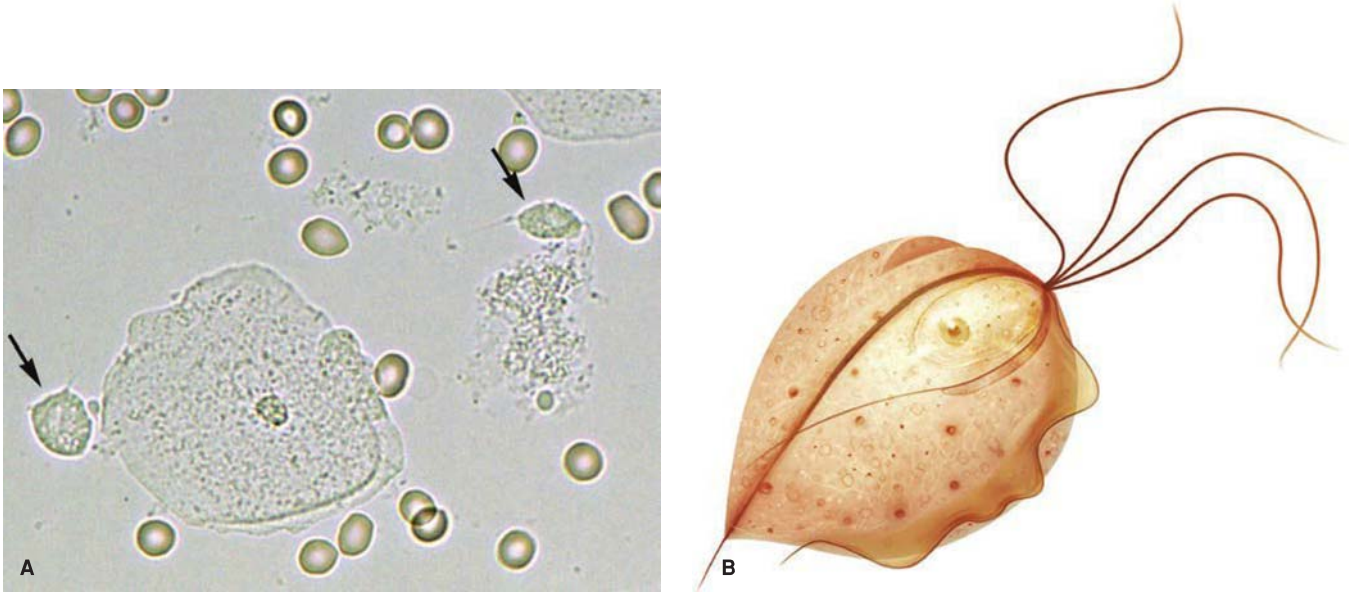

FIGURE 3-6 Trichomonads. **A.** Photomicrograph of a vaginal smear saline preparation containing trichomonads (*arrows*). (Reproduced with permission from Dr. Lauri Campagna and Rebecca Winn, WHNP.) **B.** Drawing depicts anatomic features of trichomonads. Flagella allow this parasite to be motile.

Although each is effective, some report that an oral 7-day treatment regimen with metronidazole 500 mg twice daily is more effective in compliant patients and produces fewer side effects (Howe, 2017). However, compliance may be poor because of longer treatment length. Up to 12 percent of patients taking oral metronidazole may have nausea or an unpleasant metallic taste. Because of drug disulfiram-like effects, patients should abstain from alcohol during use and for 24 hours following metronidazole therapy and for 72 hours after tinidazole.

Affected women who become asymptomatic or who are initially asymptomatic do not require routine reevaluation. However, recurrences occur in approximately 30 percent of patients. Importantly, NAATs cannot distinguish live from dead (adequately treated) trichomonads. Thus, repeat NAAT testing is ideally delayed for 3 weeks following treatment (Williams, 2014). Sex partners are encouraged to seek treatment, and patients are reminded to abstain from sex until they and their partners are cured. Condom use may be protective.

Infrequently, patients may have strains that are highly resistant to metronidazole, but these organisms are usually sensitive to tinidazole. If cure is not achieved by a single dose or then by a subsequent 7-day course of metronidazole, oral tinidazole 2 g daily for 7 days is considered. If treatment fails following adherence to multiple 1-week regimens and reinfection is excluded, culture and susceptibility testing is considered with the assistance of CDC (404-718-4141). Cases of allergy to these two nitroimidazoles require desensitization by a specialist (Helms, 2008).

SUPPURATIVE CERVICITIS

Neisseria Gonorrhoeae

N gonorrhoeae is a gram-negative coccobacillus that invades columnar and transitional epithelial cells of the cervix while sparing the vaginal squamous epithelium. Many women with cervical *N gonorrhoeae* are asymptomatic. For this reason, women at risk are screened periodically. Risk factors for gonococcal carriage and potential upper reproductive tract infection that merit screening are: age ≤24 years, prior or current STDs, new or multiple sexual partners, a partner with other concurrent partners, a partner with an STD, lack of barrier protection in those without a monogamous relationship, and commercial sex work (U.S. Preventive Services Task Force, 2014). Screening for women at low risk is not recommended.

Diagnosis

Symptomatic lower female reproductive tract gonorrhea can present as vaginitis or cervicitis. Those with cervicitis commonly describe a profuse, odorless, nonirritating, and white-to-yellow vaginal discharge. Microscopic inspection of secretions in a saline preparation typically reveals ≥20 WBCs per high-power field. Patients may report intermenstrual or postcoital vaginal bleeding. Gentle passage of a cotton swab into the cervical os often produces endocervical bleeding. Gonococcus can also infect the Bartholin and Skene glands, as well as the urethra, and ascend into the endometrium and fallopian tube to cause upper reproductive tract infection.

For gonococcal identification, NAATs are available and have replaced culture in most laboratories. Previously, acceptable specimens were recovered only from the endocervix or urethra. However, NAAT collection kits are now available for collection from the vagina, endocervix, or urine. For women without a cervix following hysterectomy, first-void urine samples are collected. For those with a cervix, vaginal-swab specimens are as sensitive and specific as cervical-swab specimens. Urine samples, although acceptable, are least preferred for those with a cervix (Centers for Disease Control and Prevention, 2014a). However, if selected, the initial urine

stream, not the midstream, is collected. Of note, these NAAT tests are not FDA-cleared for diagnostic identification of rectal or pharyngeal disease, and laboratories must establish performance specifications to meet standards for NAAT testing of these extragenital specimens. If NAAT is not available for these specimen types, cultures are obtained for rectal and pharyngeal specimens. In women with vaginal symptoms and who practice anal intercourse, consideration is given to rectal screening. One study of urban STD clinics found that approximately 20 percent of rectal chlamydia and gonorrhea infections would be missed if only cervical, vaginal, or urine samples were obtained (Llata, 2018).

Treatment

CDC recommendations for dual therapy of uncomplicated cervical, urethral, or rectal infection are outlined in Table 3-7. Importantly, widespread quinolone-resistant gonococci in the United States prompted removal of this antibiotic class from the CDC STD guidelines, and declining effectiveness of cefixime has shifted its role to an alternative agent (Centers for Disease Control and Prevention, 2015). Uncomplicated gonococcal pharyngeal infection treatment mirrors the recommended regimen in Table 3-7. Test-of-cure cultures are not usually necessary unless an alternative to ceftriaxone is used to treat pharyngeal gonorrhea infection.

In cases of cephalosporin allergy, one potential option is single oral doses of gemifloxacin 320 mg plus azithromycin 2 g. Another is single doses of gentamicin 240 mg IM plus oral azithromycin 2 g. For azithromycin allergy, ceftriaxone alone suffices. However, if the alternative regimen with cefixime is used, then doxycycline, 100 mg orally twice daily for 7 days, replaces the azithromycin (Centers for Disease Control and Prevention, 2015). Abstinence is practiced until therapy is completed and until women and their treated sexual partners have symptom resolution. Screening for reinfection is now recommended 3 months after treatment or at the next opportunity within 12 months following treatment. Earlier test-of cure-sampling is not recommended and risks identifying dead, treated gonococci.

To prevent and control STDs, guidelines for expedited partner therapy (EPT) have been created by the CDC. EPT is the delivery of a prescription by persons infected with an STD to their sexual partners without clinical assessment of the partners. EPT ideally does not replace traditional strategies, such as standard patient referral, when these are available. Although acceptable for treatment of heterosexual contacts with gonorrhea or chlamydial infection, data do not support EPT for trichomoniasis or syphilis. Although sanctioned by the CDC, EPT is not legal in some states within the United States. Moreover, the risk of litigation in the event of adverse outcomes may be elevated when a practice has uncertain legal status or is outside formally accepted community practice standards (Centers for Disease Control and Prevention, 2006). The legal status of EPT in each of the 50 states can be found at: www.cdc.gov/std/ept/legal/default.htm.

TABLE 3-7. Single-Dose Treatment of Uncomplicated Gonococcal Infection of the Cervix, Urethra, or Rectum[a]

Recommended regimen
Ceftriaxone (Rocephin) 250 mg IM[b]
PLUS
Azithromycin (Zithromax) 1 g orally once
Alternative regimen
Cefixime (Suprax) 400 mg orally once
PLUS
Azithromycin 1 g orally once

[a]Test of cure is not required. Persons with persistent symptoms of gonococcal infection or whose symptoms recur shortly after treatment are reevaluated by culture for *N gonorrhoeae*. If positive, isolates are submitted for resistance testing. Suspected treatment failures are reported to the CDC within 24 hours.
[b]Other cephalosporin options include: (1) ceftizoxime (Cefizox) 500 mg IM, (2) cefoxitin (Mefoxin) 2 g IM given with probenecid 1 g orally, or (3) cefotaxime (Claforan) 500 mg IM.
From the Centers for Disease Control and Prevention, 2015.

Chlamydia Trachomatis

This organism is among the most prevalent of the STD species recovered in the United States. Its prevalence is highest in individuals <25 years, and this was 4.3 percent in national survey estimates from 2013 to 2017 (Centers for Disease Control and Prevention, 2018a). Since many with this organism are asymptomatic, women with the same risks that prompt gonococcal screening, listed in the last section, are screening candidates.

This obligate intracellular parasite is dependent on host cells for survival. It infects columnar epithelial cells, and endocervical glandular infection leads to mucopurulent discharge or endocervical secretions. If infected, the endocervical tissue is commonly edematous and hyperemic. Urethritis also can develop, and dysuria is prominent.

Microscopic inspection of secretions in a saline preparation typically reveals ≥20 WBCs per high-power field. Also, NAAT, culture, and enzyme-linked immunosorbent assay (ELISA) are available for endocervical specimens. Of these, NAAT is recommended for its high sensitivity and specificity and technical feasibility. Also, combined gonococcal and chlamydial tests are widely used. As with gonorrhea testing, newer NAAT collection kits permit specific collection from the vagina, the endocervix, or urine (p. 66). Vaginal-swab specimens are as sensitive and specific as cervical-swab specimens. Urine samples, although acceptable, are least preferred for women with a cervix. However, for women following hysterectomy, first-void urine samples are preferred. Again, these molecular tests are not FDA-cleared for diagnostic identification of rectal or pharyngeal disease, but some laboratories have established specifications for performance of the test in extragenital specimens. As noted earlier, rectal screening is considered for women with vaginal symptoms and who practice anal intercourse.

TABLE 3-8. Oral Treatments of Chlamydial Infection

Recommended regimen
Azithromycin 1 g once
or
Doxycycline 100 mg twice daily for 7 days

Alternative regimens
Erythromycin base 500 mg four times daily for 7 days
or
Erythromycin ethyl succinate 800 mg four times daily for 7 days
or
Levofloxacin (Levaquin) 500 mg once daily for 7 days
or
Ofloxacin (Floxin) 300 mg twice daily for 7 days

From Centers for Disease Control and Prevention, 2015.

Recommended therapy for *C trachomatis* infection is described in Table 3-8. Azithromycin has the obvious therapeutic compliance advantage. Azithromycin is a broad-spectrum macrolide antibiotic with activity against many gram-positive and gram-negative bacteria. Mean concentrations in tissue are manyfold higher than those reached in serum and persist for several days (Parnham, 2014).

After therapy, women treated for chlamydial infection are retested 3 months after treatment or at the next opportunity up to 12 months following treatment. Abstinence is recommended until a woman and her partner(s) are treated and are asymptomatic. As with gonorrhea in heterosexual partners, EPT is sanctioned by the CDC for selected patients (p. 67).

Mycoplasma Genitalium

This bacterium has only recently been considered significant as a potential public health risk for its role in female reproductive tract pathology (Weisenfeld, 2017). Most female carriers are asymptomatic, but it has been linked in some but not all studies to urethritis, cervicitis, PID, and tubal-factor infertility (Lis, 2015). Thus, in women with persistent or recurrent urethritis, cervicitis, or PID, *M genitalium* is considered. It has a much more established role in male urethritis (Daley, 2014). As such, gynecologists may more frequently encounter the exposed female partner of an infected male.

In prevalence studies, *M genitalium* is common in groups at risk for STDs (Getman, 2016; Trent, 2018). However, a consensus on screening criteria is hindered by lack of a NAAT that is FDA-approved and available outside a research setting. Currently, the CDC (2015) comments that NAAT testing for women exposed to *M genitalium* and treatment of subsequently identified infections can be considered. In Europe, NAATs for this organism are more widely available. Guidelines there for testing include women with STD exposure or symptoms of infection (Jensen, 2016). In these cases, samples from voided urine, the vagina, or the endocervix are appropriate (Lillis, 2011).

Without specific diagnostic testing, women are often empirically treated for persistent urethritis or cervicitis or for *M genitalium* exposure. Azithromycin 1 g orally once is recommended and is more effective than doxycycline. Antibiotic-resistant strains are not uncommon, and for treatment failure, moxifloxacin 400 mg orally once daily for 7 to 14 days may be used. This same moxifloxacin regimen for 14 days may be considered for women with PID who fail to respond after 7 to 10 days of standard regimens and in whom *M genitalium* is detected (Centers for Disease Control and Prevention, 2015; Manhart, 2015).

PELVIC INFLAMMATORY DISEASE

With this infection of the upper female reproductive tract, all reproductive tract organs may be involved. However, the organ of importance, with or without abscess formation, is the fallopian tube. Because tubal-factor infertility, ectopic pregnancy, and chronic pelvic pain are known sequelae of clinical and subclinical infection, clinicians ideally carry a low threshold for diagnosing and treating PID. The true prevalence of PID is unknown, due to difficulty in accurately diagnosing pelvic infection. Among females aged 15 to 44 years, the self-reported prevalence rate in 2013 was 4 percent, which was lower than the rate in 1995 (8.6 percent) (Kreisel, 2017; Leichliter, 2013). Greater STD screening is one suggested cause for this decline (Nelson, 2001; Owusu Edusei, 2010).

PID may be classified as acute, subclinical, or chronic. Acute PID, which is defined as lasting <30 days, represents most cases. Chronic PID is generally associated with *Mycobacterium tuberculosis* or *Actinomyces* species and is described later (p. 72).

Microbiology and Pathogenesis

Classic acute PID is associated with and secondary to *N gonorrhoeae* infection, and *C trachomatis* also can be recovered. The gonococcus incites a direct inflammatory response in the human endocervix, endometrium, and fallopian tube and is one of the true pathogens of human fallopian tube epithelial cells. In contrast, intracellular *C trachomatis* does not cause an acute inflammatory response, and little *direct* permanent damage results from chlamydial tubal involvement (Patton, 1983). However, cell-mediated immune mechanisms may be responsible for later tissue injury (Tiitinen, 2006). Specifically, persistent chlamydial antigens can trigger a delayed hypersensitivity reaction with continued tubal scarring and destruction (Toth, 2000). Another species frequently found is *T vaginalis*. The presence of *M genitalium* in women with PID has been described, but its pathogenesis is less well understood (Baczynska, 2007; Short, 2009). In sum, risks for PID mirror those for STDs. Also, the lower reproductive tract flora in women with PID and in those with BV includes predominately anaerobic species. PID shares an association with BV, but causation is unclear (Ness, 2004, 2005).

Despite the association between PID and chlamydial infection or gonorrhea, many cases of PID are culture-negative for an STD (Burnett, 2012; Goller, 2017). In these cases, upper tract infection is believed to be caused by bacteria that ascend

from the lower reproductive tract. Ascension is enhanced by loss of endocervical barriers that can accompany menstruation, BV, and gonococcal or chlamydial infection. Last, direct extension from inflammatory GI disease, especially a ruptured appendiceal or diverticular abscess, for example, also can lead to salpingitis and PID.

Diagnosis

Subclinical Pelvic Inflammatory Disease

Subclinical PID is an upper genital tract infection without symptoms. It is an ultimate diagnosis given to women with tubal-factor infertility who lack a history compatible with acute PID (Wiesenfeld, 2005, 2012). Many of these patients have antibodies to *C trachomatis* and/or *N gonorrhoeae* (Sellors, 1988; Tjiam, 1985). At laparoscopy or laparotomy, affected women may have evidence of prior tubal infection such as adhesions or hydrosalpinges, but for the most part, the fallopian tubes are grossly normal. Internally, however, tubes show flattened mucosal folds, extensive deciliation of the epithelium, and secretory epithelial cell degeneration (Patton, 1989).

Acute Pelvic Inflammatory Disease

Symptoms and Physical Findings. Acute PID is diagnosed if uterine tenderness, adnexal tenderness, *or* cervical motion tenderness is present and other etiologies are excluded or unlikely. One or more of the following enhances diagnostic specificity: (1) oral temperature >38.3°C (101.6°F), (2) mucopurulent cervical discharge or cervical friability, (3) abundant WBCs on saline microscopy of cervical secretions, (4) elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), and (5) presence of cervical *N gonorrhoeae* or *C trachomatis* (Centers for Disease Control and Prevention, 2015). Thus, a diagnosis of PID is typically based on clinical findings.

Symptoms of acute PID characteristically develop during or following menstruation. These can include lower abdominal and/or pelvic pain, yellow or green vaginal discharge, heavy menstrual bleeding, fever, nausea, vomiting, diarrhea, dysmenorrhea, and dyspareunia. Patients also may have complaints suggesting urinary tract infection (UTI). Unfortunately, no single symptom is associated with a physical finding that is specific for this diagnosis. Accordingly, other possible sources of acute pelvic pain are considered and listed in Table 12-1 (p. 255).

Of findings, mucopurulent endocervicitis is common and is diagnosed visually and microscopically. During bimanual pelvic examination, affected women will usually have pelvic organ tenderness. Cervical motion tenderness (CMT) is typically elicited by quickly moving the cervix with examining vaginal fingers. This reflects pelvic peritonitis and can be considered a vaginal "rebound" test. If a woman has pelvic peritonitis secondary to bacteria and pus that has exuded from the fimbriated end of the fallopian tube into the pelvis, this rapid peritoneal movement usually causes a marked pain response. Tapping the posterior cul-de-sac with an examining finger will give the examiner similar information. This latter maneuver usually causes a patient significantly less pain because less inflamed peritoneum is stretched.

Abdominal peritonitis may be identified by deep palpation and quick release of a hand placed on the abdomen—a test for rebound. Alternatively, an examining hand may be positioned with a palm against a woman's midabdomen and gently and quickly moved back and forth (shake). This can identify abdominal peritonitis, often with less patient discomfort.

In women with PID and peritonitis, usually only the lower abdomen is involved. However, inflammation of the liver capsule, which can accompany PID, may lead to right upper quadrant pain, a condition known as *Fitz-Hugh-Curtis syndrome*. Classically, symptoms of this perihepatitis include sharp, pleuritic right upper quadrant pain that accompanies pelvic pain. The upper abdominal pain may refer to the shoulder or upper arm. Importantly, during examination, if all abdominal quadrants are involved, suspicion for a ruptured tuboovarian abscess (TOA) is heightened.

Testing. For reproductive-aged women, pregnancy complications can be identified by serum or urine beta–human chorionic gonadotropin testing. A complete blood count (CBC) is selected as a baseline test to help exclude hemoperitoneum and identify WBC elevation. In those with significant nausea and vomiting or Fitz-Hugh-Curtis syndrome, liver enzyme values can be normal or mildly elevated. If properly collected, urinalysis findings for infection will be absent. Saline preparation of cervical or vaginal discharge typically shows sheets of WBCs. In women with suspected acute PID, endocervical testing for both *N gonorrhoeae* and *C trachomatis* is performed as described earlier (p. 66). Screening for other STDs also is completed. Although an endometrial biopsy that reveals acute endometritis is a specific criterion, this is mainly used in research settings. In general, the delay between collection and reporting precludes its clinical utility.

Sonography. In women with marked abdominal pain and tenderness, appreciation of upper reproductive tract organs during bimanual examination may be limited, and sonography is a primary imaging tool. Normal fallopian tubes are rarely imaged. However, with acute tubal inflammation, the tube swells, its lumen occludes distally, it distends, and its walls and endosalpingeal folds thicken. Characteristic acute findings include: (1) distended, ovoid-shaped tube filled with anechoic or echogenic fluid, (2) fallopian tube wall thickening, (3) incomplete internal septa, and (4) a "cogwheel" appearance when inflamed tubes are imaged in cross section (Timor-Tritsch, 1998) (Fig. 3-7). If color or power Doppler is applied, marked vascularity with low-impedance blood flow, which reflects hyperemia, is seen within thickened fallopian tube walls and septa (Molander, 2001; Romosan, 2013). Sonography also may be used to identify a TOA or exclude other pathology as the pain source. If sonography does not lead to a clear diagnosis, computed tomography (CT) scanning may be useful and especially with right upper quadrant pain suggestive of perihepatitis (Kim, 2009). Classic findings of acute PID on CT imaging include fallopian tube thickening and pelvic fat stranding (Jung, 2011). Magnetic resonance (MR) imaging is a suitable, although infrequently used, alternative.

Laparoscopy. Historically, in Scandinavian countries, women with suspected PID underwent laparoscopy for diagnosis. Tubal serosal hyperemia, tubal wall edema, and purulent exudate issuing

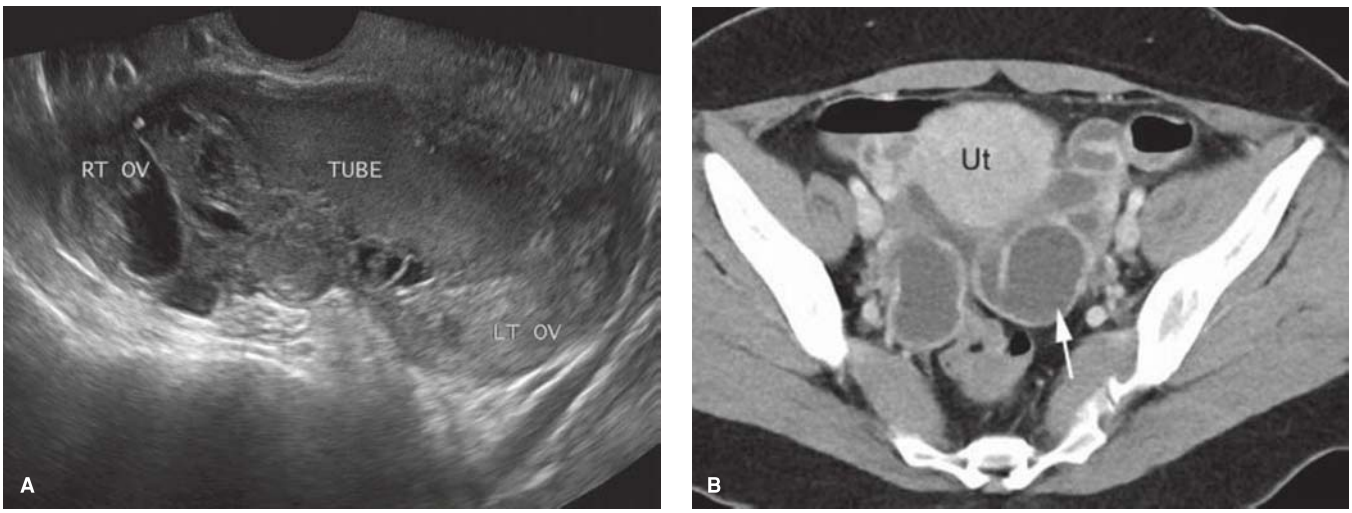

FIGURE 3-7 Pyosalpinx. **A.** Transvaginal sonogram shows a pyosalpinx and both ovaries as part of a tuboovarian complex. **B.** Computed tomography image shows a tortuous pyosalpinx (*arrow*) adjacent to the uterus (*Ut*).

from the fimbriated ends of the fallopian tubes, termed *pyosalpinx*, and pooling in the cul-de-sac confirmed this diagnosis. Because of this routine practice, Hadgu and coworkers (1986) assembled criteria that preoperatively clinically predicted acute PID and assessed their validity by the absence or presence of PID at laparoscopy. Criteria included: (1) single status, (2) adnexal mass, (3) age <25 years, (4) temperature >38°C, (5) cervical *N gonorrhoeae*, (6) purulent vaginal discharge, and (7) ESR ≥15 mm/hr. The preoperative clinical diagnosis of PID was 97-percent accurate if a woman met all seven criteria. Thus, due to the risks of laparoscopy, use of clinical findings alone to diagnose PID is reasonable. In those with a less clear presentation, laparoscopy may be needed to exclude other pathology such as appendicitis or adnexal torsion.

Tuboovarian Abscess

With infection, the inflamed and suppurative fallopian tube can adhere to the ovary. Sonographically, if both tube and ovary are recognizable, the term *tuboovarian complex* is used. If inflammation proceeds, tissue planes and distinction between the two is lost, and the term *tuboovarian abscess* is applied. TOAs are typically unilateral and may also involve adjacent structures that include bowel, bladder, and contralateral adnexa. With abscess progression, further structural weakening may lead to abscess rupture and potentially life-threatening peritonitis. Although PID is an important cause of TOA, these may also follow appendicitis, diverticulitis, inflammatory bowel disease, or surgery.

Classically, women with a TOA display signs of PID, and a concurrent adnexal or cul-de-sac mass is palpable. Sonographically, the mass has thick irregular walls, areas of mixed echogenicity, septations, and internal echoes from debris (see Fig. 3-7). If the clinical picture is unclear, CT scanning may add information. In addition to those qualities just described, the mass often shows surrounding inflammatory changes with CT imaging. Periappendiceal abscess is a common mimic. Findings favoring TOA include the right ovarian vein entering the mass, the mass lying posterior to the mesovarium, contralateral pelvic fat stranding, and thickened uterosacral ligaments (Hiller, 2016). MR imaging usually shows a complex pelvic mass with low signal intensity on T1-weighted sequences and heterogeneously high signal intensity on T2-weighted sequences. MR imaging is not routinely used for TOA diagnosis but may be helpful and shows greater accuracy than CT scanning for distinguishing TOAs from ovarian neoplasms (Fan, 2018).

Microorganisms frequently cultured from abdominal specimens include *Escherichia coli* and *Bacteroides*, *Peptostreptococcus*, and *Streptococcus* species (Landers, 1983). Thus, broad-spectrum antibiotics that include anaerobic coverage are selected for initial management of an unruptured TOA. Most women with a TOA will respond to IV antibiotic therapy alone and avoid the need for drainage. Combination antimicrobial regimens will predictably be more successful, and CDC (2015) recommendations for TOA complicating PID include the IV regimens in Table 3-9.

TABLE 3-9. Recommended Parenteral Treatment of PID

Recommended regimens

Cefotetan (Cefotan) 2 g IV every 12 hr
or
Cefoxitin (Mefoxin) 2 g IV every 6 hr
PLUS
Doxycycline 100 mg orally or IV every 12 hr

OR

Clindamycin 900 mg IV every 8 hr
PLUS
Gentamicin loading dose 2 mg/kg IV or IM followed by a maintenance dose of 1.5 mg/kg every 8 hr. Single daily dosing at 3 to 5 mg/kg per day may be substituted.

Alternative regimen

Ampicillin/sulbactam (Unasyn) 3 g IV every 6 hr
PLUS
Doxycycline 100 mg orally or IV as above

IV = intravenous; PID = pelvic inflammatory disease.
From Centers for Disease Control and Prevention, 2015.

Parenteral antimicrobial therapy is continued until the patient has been afebrile for at least 24 hours, preferably 48 to 72 hours. In transitioning to oral therapy, doxycycline 100 mg twice daily is combined with either metronidazole 500 mg twice daily or clindamycin 450 mg four times daily to complete a 14-day course.

For those not improved within 2 to 3 days of treatment, antimicrobial regimen modification is reasonable. Alternatively, drainage may provide a specimen to guide antibiotic tailoring. Moreover, drainage plus antibiotic therapy can be considered as initial treatment for larger abscesses (≥7 cm) (Dewitt, 2010; Gjelland, 2005; Reed, 1991). Evacuation can be accomplished with or without surgery. Radiologic drainage is minimally invasive and potentially avoids the higher risks associated with general anesthesia and surgery. In general, pelvic collections can be drained using transabdominal, transvaginal, transgluteal, or transrectal techniques with either CT or sonographic guidance and adequate analgesia (Fig. 3-8). Depending on abscess size and characteristics, contents can be removed with needle aspiration or with pigtail catheter placement and short-term drainage. Contraindications are an unsafe pathway to the abscess, hemodynamic instability, or significant uncorrectable coagulopathy (American College of Radiology, 2018). In cases that are refractory or not amenable to these more conservative measures, exploratory laparoscopy or laparotomy is typically warranted. In women with acute TOA rupture, emergency surgery is required, and goals are abscess drainage, necrotic tissue excision, and peritoneal cavity irrigation.

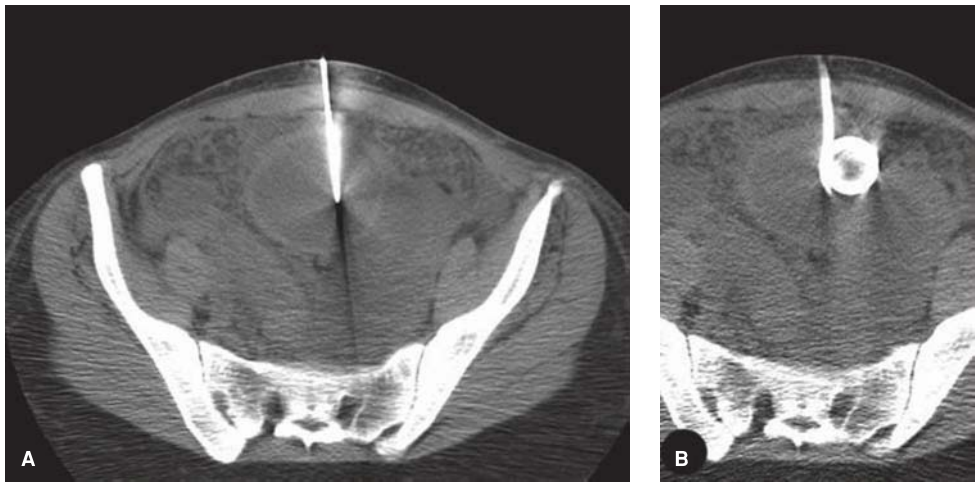

FIGURE 3-8 Tuboovarian abscess. **A.** Computed tomographic (CT) scan demonstrating percutaneous drainage of a tuboovarian abscess. **B.** The pigtail catheter coils to remain in place to allow continuous drainage.

As is true in all abscesses, drainage is the key to clinical improvement. Although perhaps tempting at laparotomy, removal of the abscessed tissue is not necessary unless ovarian parenchyma is involved. This is rare. Electively opening the protective peritoneal and other tissue planes to remove tissues—especially the uterus—in the presence of acute infection does not improve patient outcome compared with percutaneous drainage. Infection confined within one organ, such as a pyosalpinx, responds more favorably to antimicrobial therapy because of adequate blood and lymphatic supply. This is true even if attached to an adjacent ovary. However, a cul-de-sac, interloop, or multiloculated abscess is more likely to require drainage. This stems from their greater tendencies for poor blood and lymphatic supply and less prompt response to antimicrobial therapy.

Treatment of Acute Pelvic Inflammatory Disease

The most successful patient outcomes follow early diagnosis and prompt, appropriate therapy. The primary therapy goal is to eradicate bacteria, relieve symptoms, and prevent sequelae. Tubal damage or occlusion resulting from infection may lead to infertility. Rates following one episode approximate 10 percent; two episodes, 20 percent; and three or more episodes, 40 percent (Westrom, 1992). Also, ectopic pregnancy risk is increased 4, 8, and 14 percent following one, two, or three episodes, respectively (Joesoef, 1991). Other sequelae include chronic pelvic pain, recurrent infection, and chronic abscess.

In-hospital parenteral antibiotic treatment is not required for all women with PID. However, some criteria predict better outcome for certain patients (Table 3-10).

Another potential clinical decision involves management of a coexistent IUD. During the first 3 weeks after insertion, patients have an increased IUD-associated PID risk. After this time, other PID risks are considered causative. In women with PID and an IUD, theoretical concerns are that the coexistent device might worsen the infection or delay resolution. Although a provider may choose to remove the device, evidence supports leaving an IUD during treatment in those with mild or moderate PID (Centers for Disease Control and Prevention, 2015; Tepper, 2013). Severe disease typically warrants IUD removal. With or without an IUD, women are treated with similar antibiotic regimens. But, if a patient fails to improve within 48 to 72 hours, the device is removed.

TABLE 3-10. Suggested Indications for Parenteral Treatment of PID

Pregnant
High fever
Suspected abscess
Uncertain diagnosis
Generalized peritonitis
Failed outpatient therapy
Noncompliant with medications
White blood cell count >15,000/mm^3
Nausea/vomiting precluding oral therapy

PID = pelvic inflammatory disease.

Oral Treatment

In women with a mild to moderate clinical presentation, outpatient treatment and inpatient therapy yield comparable results. Clinical treatment with oral therapy is also appropriate for women with HIV infection and PID. This group has the same species recovered compared with non-HIV-infected patients, and their response to therapy is similar.

If women have more than moderate disease, they require hospitalization. For women with outpatient treatment, one study showed that women treated as outpatients took 70 percent of prescribed doses, and for less than 50 percent of their outpatient treatment days (Dunbar-Jacob, 2004). Thus, if patients are treated as outpatients, an initial parenteral dose may be beneficial. Women treated as outpatients are reevaluated in approximately 72 hours by phone or in person. If women do not respond to oral therapy within 72 hours, parenteral therapy is initiated either as an inpatient or as an outpatient if home nursing care is available. This assumes that the diagnosis is confirmed at reevaluation.

Specific oral treatment recommendations from the CDC are found in Table 3-11. Anaerobes are believed by some to play an important role in upper tract infection and are treated. Hence, metronidazole may be added to improve anaerobic coverage. If patients have BV or trichomoniasis, then metronidazole addition is required, although perhaps not for 14 days.

Parenteral Treatment

Any woman who has criteria as outlined in Table 3-10 is hospitalized for parenteral treatment for at least 24 hours. Following this, if home parenteral treatment is available, this is a reasonable option. Alternatively, a woman who responds clinically to initial parenteral antibiotics may be discharged on one of the oral regimens in Table 3-11.

Recommendations for parenteral antibiotic treatment of PID are found in Table 3-9. Of these antibiotics, oral and parenteral routes of doxycycline have almost identical bioavailability, but parenteral doxycycline is caustic to veins. Many prospective clinical trials have shown that either of the listed cephalosporins alone, without doxycycline, will result in a clinical cure. For that reason, doxycycline administration could be reserved until the patient can take oral medication. Parenteral therapy is continued for 24 hours after the patient clinically improves. The oral doxycycline 100 mg twice daily is continued to complete 14 days of therapy. Alternatively, if the IV gentamycin/clindamycin regimen is used, transition to a 14-day oral agent may involve clindamycin orally four times daily or doxycycline 100 mg twice daily.

TABLE 3-11. Outpatient Treatment of PID

Ceftriaxone (Rocephin) 250 mg IM once[a,b]
PLUS
Doxycycline 100 mg orally twice daily for 14 days
with or without
Metronidazole (Flagyl) 500 mg orally twice daily for 14 days

[a]Cefoxitin (Mefoxin) 2 g IM with 1 g oral probenecid once may replace ceftriaxone.
[b]Other parenteral third-generation cephalosporin IM given in a single dose such as ceftizoxime or cefotaxime may replace ceftriaxone.
IM = intramuscular; PID = pelvic inflammatory disease.
From Centers for Disease Control and Prevention, 2015.

Chronic Pelvic Inflammatory Disease

This is defined as PID lasting longer than 30 days, and one cause is *Actinomyces israelii.* This is a gram-positive, slow-growing, anaerobic bacterium found to be part of the indigenous genital flora of healthy women (Persson, 1984). Pelvic infection and abscess are rare, even in those identified to harbor the bacteria.

With infection, findings include fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge. Actinomyces is sensitive to penicillins. Prolonged parenteral antibiotic administration is required for 4 to 6 weeks followed by oral antibiotics for 6 to 12 months.

Some have found *Actinomyces* species more frequently in the vaginal flora of IUD users, and rates of colonization rise with duration of IUD use (Curtis, 1981). *Actinomyces* is also identified in Pap smears, and Fiorino (1996) cited a 7-percent incidence in IUD users compared with <1 percent in nonusers. In the absence of symptoms, the incidental finding of *Actinomyces* in a Pap sample may be managed conservatively. Other suitable options include extended oral antibiotic treatment with the IUD in place, IUD removal, or IUD removal followed by antibiotic treatment (American College of Obstetricians and Gynecologists, 2017a). Reviews by Lippes (1999) and Westhoff (2007) support IUD retention and observation. If signs or symptoms of infection do develop in a woman who harbors *Actinomyces*, the device is removed and antimicrobial therapy is instituted.

Although rare in the United States, salpingitis and endometritis can originate from pulmonary tuberculosis. *Mycobacterium tuberculosis* is thought to be blood-borne, but ascension may still be a possible route. Importantly, with infection, an associated pelvic mass, ascites, omental inflammation, and peritoneal studding or thickening may mimic peritoneal spread of malignancy. Once diagnosed, treatment is best coordinated with an infectious disease specialist.

INFECTIOUS WARTS AND PAPULES

External Genital Warts

These lesions originate from human papillomavirus (HPV) infection, and 86 percent of genital wart cases stem from HPV 6 or 11 (Garland, 2009). From one large insurance database, the incidence ranged from 0.1 to 0.3 percent in reproductive-aged women (Flagg, 2018). Logically, genital wart incidence is lowest in those previously vaccinated against HPV. Genital wart prevention is one indication for the nonavalent vaccine (Gardasil), which protects against 9 HPV serotypes, including 6 and 11 (Table 1-4, p. 9).

Genital warts appear as flat papules or classic verrucous, exophytic lesions, termed *condyloma acuminata* (Fig. 3-9)

FIGURE 3-9 Condyloma acuminata. Multiple exophytic verrucous warts are seen on the labia and perineum.

(Beutner, 1998). External genital warts can develop at sites in the lower reproductive tract, urethra, anus, or mouth. They are usually asymptomatic but can be pruritic or painful depending on their size and location. Warts are typically diagnosed by clinical inspection. Biopsy is not required unless coexisting neoplasia is suspected, the diagnosis is unclear, or the patient is immunosuppressed (Park, 2015). Similarly, HPV serotyping is not required for routine diagnosis.

Condyloma acuminata may remain unchanged or spontaneously resolve, and the effect of treatment on future viral transmission is unclear. However, many women prefer removal, and lesions can be removed or destroyed with sharp excision, electrosurgical needle-tip excision, cryotherapy, or laser ablation. Alternatively, topical agents can be applied to resolve lesions (Table 3-12). One of these, 5-percent imiquimod cream (Aldara), is an immunomodulatory topical treatment for genital warts (Yan, 2006). Also, a 3.75-percent imiquimod cream (Zyclara) is effective (Baker, 2011). Imiquimod enhances local production of immune-stimulating cytokines to promote a response against HPV (Miller, 1999). Another topical immune-modulating agent is a 15-percent sinecatechins ointment (Veregen) derived from green tea leaf extracts (Meltzer, 2009; Tatti, 2008). Podofilox, also termed podophyllotoxin, is an antimitotic agent that disrupts viral activity by inducting local tissue necrosis. Available in a 0.5-percent solution or gel (Condylox), it can be self-applied by the patient (Komericki, 2011; Yan, 2006). The more concentrated 10 to 25-percent podophyllin resin is no longer a recommended regimen due to risks of systemic toxicity. Of other agents, trichloroacetic acid and bichloroacetic acid are proteolytic and are applied serially to warts. Intralesional interferon, photodynamic therapy, or topical cidofovir are second-tier alternative regimens listed by the CDC (2015). All topical treatments in this section can result in skin irritation, which at times may require treatment breaks.

Of therapy choices, no data suggest the superiority of one treatment. Thus, in general, treatment is selected based on clinical circumstances and patient and provider preferences (Werner, 2017). Importantly, no treatment option, even surgical excision, boasts 100-percent clearance rates. Indeed, clearance rates range from 30 to 80 percent. Accordingly, recurrences are common following treatment, particularly in women with HIV. Biopsy is considered for atypical or recalcitrant lesions, which may harbor concomitant intraepithelial neoplasia (Massad, 2011).

TABLE 3-12. Recommended Treatment of External Genital Warts

Patient-applied

Imiquimod 5% cream (Aldara). Apply a thin layer and rub until absorbed once daily at bedtime, three times a week, up to 16 wks. After 6 to 10 hr, the area is washed with soap and water.

or

Imiquimod 3.75% cream (Zyclara). Apply a thin layer once daily at bedtime, up to 8 wks. After 8 hr, the area is washed with soap and water.

or

Podofilox 0.5% solution or gel (Condylox). Apply the solution with a cotton swab or the gel with a finger to genital warts twice daily for 3 d, followed by 4 d of no therapy. This cycle is repeated up to four cycles. The area treated does not exceed 10 cm^2, and the total volume of podofilox is limited to 0.5 mL/d.

or

Sinecatechins 15% ointment (Veregen). Apply a 0.5-cm strand to each wart with a finger three times daily, up to 16 wks. It is not washed off, and sexual contact is avoided when ointment is present.

Provider-administered

Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1 to 2 wks.

or

Trichloroacetic acid (TCA) or **bichloroacetic acid** (BCA) 80 to 90 percent. Apply a small amount only to the warts and allowed to dry, which creates a white "frosting." This is repeated weekly if necessary. If an excess amount is applied, the treated area is powdered with talc, baking soda, or liquid soap to remove unreacted acid.

or

Surgical removal by scissor, shave excision, curettage, or electrosurgery needle.

FIGURE 3-10 Molluscum contagiosum. Labial lesions are flesh-colored, dome-shaped papules with central umbilication.

Molluscum Contagiosum

This skin infection is caused by the molluscum contagiosum virus, which is transmitted by direct human-to-human contact or by infected fomites. Molluscum contagiosum is contagious until lesions resolve, and an incubation period of 2 to 7 weeks is typical. Infection gives rise to multiple, 2- to 5-mm, flesh-colored papules with central umbilication (Fig. 3-10). These are commonly found on the vulva, thighs, or buttocks.

These papules are typically diagnosed by visual inspection alone. With an unclear diagnosis, biopsy is considered. Histologically, the classic cup-shaped lesion has normal basal layers but surface keratinocytes acquire eosinophilic *molluscum bodies* that contain virus particles. Alternatively, material from a lesion can be collected on a swab, applied to a slide, and submitted for diagnostic staining. With this, molluscum bodies are diagnostic.

Most lesions spontaneously regress within 6 to 12 months. If removal is preferred, lesions may be treated by cryotherapy, electrosurgical needle coagulation, or sharp needle-tip curettage of a lesion's umbilicated center. These methods have not demonstrated superior results compared with spontaneous healing. Some topical agents used for genital warts may be considered (Tyring, 2003). However, no single treatment is superior. Of these, topical imiquimod is ineffective and may cause severe application-site reactions (van der Wouden, 2017).

PRURITIC INFESTATIONS

Scabies

Sarcoptes scabiei infects skin and result in an intensely pruritic rash. This mite is crab-shaped, and the female digs into the skin and remains there for approximately 30 days, elongating her burrow. Several eggs are laid daily and begin hatching after 3 to 4 days. The baby mites furrow their own burrows, becoming reproductive adults in approximately 10 days. The number of adult mites present on an affected patient averages a dozen. Sexual transmission is the most likely cause of initial infection, but household contacts can become infected. Shared or crowded housing is another risk.

Burrows are thin elevated skin tracks measuring 5 to 10 mm in length. A delayed hypersensitivity reaction (type 4) to the mites, eggs, and feces develops and results in erythematous papules, vesicles, or nodules in association with skin burrows. Secondary infection, however, may develop and hide these tracks. Most common infestation sites include the hands, wrist, elbows, groin, and ankles. Itching and dermatologic changes in these areas are the predominant symptoms.

Definitive testing requires scraping across the burrow with a scalpel blade and mixing these fragments in immersion oil on a microscope slide. Identification of mites, eggs, egg fragments, or fecal pellets is diagnostic (Fig. 3-11). For treatment, 5-percent permethrin cream (Elimite) is a recommended agent. A thin layer is applied from the neck downward with special attention to pruritic areas and the hands, feet, and genital regions. Ideally, all family members are treated with the exception of infants younger than 2 years. Eight to 14 hours after application, a shower or bath is taken to remove the medication. Only one application is necessary. Another option is a 200-µg/kg single oral dose of ivermectin (Stromectol) given initially and then repeated 2 weeks later. Bed linens and recently worn clothing

FIGURE 3-11 Microscopic images of *Sarcoptes scabiei*. **A.** A mite is seen prior to hatching. **B.** Hatched mite. **C.** Remnant egg casings following hatching and smaller fecal particles.

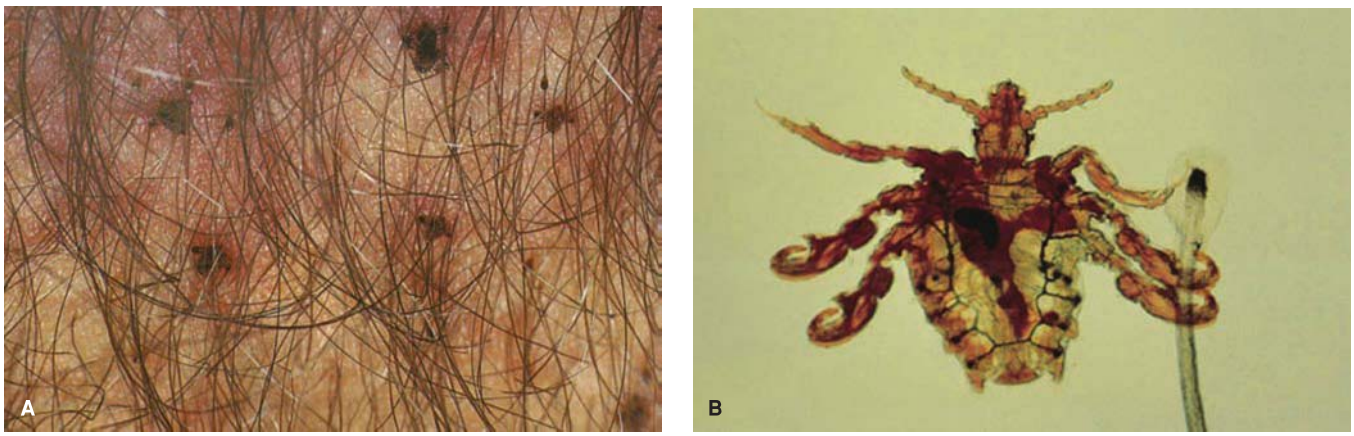

FIGURE 3-12 *Phthirus pubis*. **A.** Pubic lice are seen attached to hair. In addition, nits are seen as dark dots adhered to pubic hair. (From Morse, 2003, with permission.) **B.** Photomicrograph of *Phthirus pubis*. Claw-like legs are ideally suited for clinging to hair shafts. (From Birnbaum, 2010, with permission.)

are washed to prevent reinfection. A 1-percent lindane lotion is less-preferred due to associated risk of seizures. An antihistamine can help reduce pruritus, which may also be treated with a hydrocortisone-containing cream in adults or with emollients in infants. If these lesions become infected, antibiotics directed against skin flora may be necessary.

Pediculosis

Lice are small ectoparasites that measure approximately 1 mm (Fig. 3-12). Three species infest humans and include the body louse (*Pediculus humanus*), the crab louse (*Phthirus pubis*), and the head louse (*Pediculus humanus capitis*). Lice attach to the base of human hair with claws that vary in diameter between species. This claw diameter determines the infestation site. For this reason, the crab louse is found on pubic hair and other hair of similar diameter, such as axillary and facial hair, including eyelashes and eyebrows. Pubic lice are usually sexually transmitted, whereas head and body lice may be transmitted by sharing personal objects such as combs, brushes, and clothing.

Each female adult pubic louse lays approximately four eggs a day, which are glued to the base of hairs. Incubation approximates 1 month. Their attached eggs, termed *nits*, can be seen attached to the hair shaft away from the skin line as hair growth progresses. These nits usually require a magnifying glass for identification. Moreover, suspicious flecks on pubic hair or in clothing can be examined microscopically to see the characteristic louse. Lice depend on frequent human blood meals, and pubic lice must travel for new attachment sites. The main symptom from louse attachment and biting is pruritus.

Some pediculicides kill only adult lice, whereas others are ovicidal as well. A single application is usually effective, but a second dose is recommended within 7 to 10 days to kill new hatches. OTC cream rinses or shampoos contain 1-percent permethrin (Nix) or pyrethrins with piperonyl butoxide (Rid, Pronto, R & C). These remain on affected areas for 10 minutes. CDC (2015) alternative regimens include 0.5-percent malathion lotion (Ovide) applied for 8 to 12 hours. Also, ivermectin, 250 μg/kg orally once, can be taken and then repeated in 2 weeks.

In selected cases, 1-percent lindane shampoo can be used, but again, this is less favored due to potential neurotoxicity. Last, eyelash and eyebrow treatment is problematic. These areas are best treated by applying petrolatum (Vaseline) with a cotton swab at night and washing it off in the morning. Bedding and infested clothing are washed and dried with a heat cycle.

In spite of treatment, pruritus may continue and can be relieved by oral antihistamines, topical antiinflammatory cream, or both. The patient is reevaluated after 1 week to document louse eradication. If lesions become secondarily infected, antibiotic therapy may be necessary. Patient screening for other STDs is encouraged. Other family members and sexual contacts require evaluation for infestation.

URINARY TRACT INFECTIONS

Acute cystitis accounts for most symptomatic bacterial lower UTIs. Women have many more UTIs than men because of their pelvic anatomy. Bacteria ascend from the short, colonized urethra and easily enter the bladder and perhaps then the kidneys. Sexual intercourse increases bladder inoculation. Also, contributing to contamination, the warm moist vulva and rectum are both in close proximity. Indeed, the bacterial species most frequently recovered from infected urine cultures is *E coli*. Other identified species are *Klebsiella pneumoniae*, *Proteus mirabilis*, and *Staphylococcus saprophyticus* (Echols, 1999; Czaja, 2007). Once in the bladder, bacteria may ascend within the ureters into the renal pelvis and cause upper tract infection. Less often, the renal parenchyma can be infected by blood-borne organisms, especially during staphylococcal bacteremia.

Acute Bacterial Cystitis

Diagnosis

With acute bacterial cystitis, frequent complaints in otherwise healthy, immunocompetent nonpregnant women are dysuria, frequency, urgency, hematuria, and incontinence. With one or more of these symptoms, the probability of infection is 50 percent. This rises to 90 percent when symptoms of vaginitis are

TABLE 3-13. Exclusions from "Uncomplicated" Cystitis

Diabetes
Pregnancy
Immunosuppression
Symptoms >7 days
Postmenopausal hematuria
Recent UTI or urologic surgery
Documented urologic abnormalities
Recent hospital or nursing home discharge
Documented temperature above 38°C (100.4°F)
Abdominal and/or pelvic pain, nausea, vomiting
Symptoms of vaginitis (vaginal discharge/vulvar irritation)
Persisting symptoms despite >3 days of treatment of urinary tract infection

UTI = urinary tract infection.

absent (Bent, 2002). If the patient prefers, most women can be treated based solely on symptoms for an isolated episode of acute uncomplicated bacterial cystitis. However, patients are instructed that fever >38°C (100.4°F) and persistence or recurrence of hematuria, dysuria, and frequency, despite treatment, merit further attention.

In women with complicated or recurrent infections or with persistent or new symptoms during treatment, physical examination can be informative (Table 3-13). For example, hematuria in a postmenopausal woman may reflect cervical, uterine, or colonic bleeding that is most evident to them at the time of urination. Similarly, burning with urination may indicate vulvitis. Coupled with examination, urinalysis and urine culture are obtained for suspected complicated infection.

For a culture specimen to be informative, it must be accurately collected. A "clean catch" midstream voided urine specimen is usually sufficient. A patient is counseled on the steps of urine specimen collection, which are designed to prevent contamination by other bacteria from the vulva, vagina, and rectum. More than one bacterial species identified in a urine culture usually indicates specimen collection contamination. Initially, a patient spreads her labia and wipes the periurethral area from front to back with an antiseptic tissue. With labia spread, she begins urinating but does not collect the initial stream. A "midstream" sample is then collected into a sterile cup. After collection, the specimen is delivered promptly to the laboratory and is plated for culture within 2 hours of collection unless it is refrigerated.

Culture. Urine culture allows accurate identification of an inciting pathogen and susceptibility testing of that pathogen to various antibiotics. Classically, significant bacteriuria is defined as $\geq 10^5$ bacteria (colony-forming units [cfu]) per milliliter of urine. If urine is collected by either suprapubic aspirate or catheterization, colony counts $\geq 10^2$ cfu/mL are diagnostic. As an exception, Hooton and coworkers (2013) demonstrated that *E coli* in midstream urine is highly predictive of bladder bacteriuria even at very low counts of 10^2 cfu/mL.

Although anaerobic bacteria are part of the vaginal, colonic, and skin flora, they rarely cause UTIs. Hence, urine culture reports do not note anaerobes unless laboratory staff is specifically instructed to look for these species. Fungi are reported but are rare causes of acute cystitis.

Culture is the gold standard, and bacterial species may be identified preliminarily, but a final urine culture report usually is not available for 48 hours. However, rapid test surrogates for culture can support a UTI diagnosis and include microscopy, nitrite testing, and leukocyte esterase testing. Empiric treatment is initially begun but is modified, as needed, after culture results are available.

Culture Surrogates. *Gram staining* is a simple, rapid, and sensitive method for detecting a concentration $\geq 10^5$ cfu/mL of a bacterial species. Rapid identification allows appropriate selection of empiric antimicrobial therapy. However, realistically, such testing is typically limited to patients with complicated UTIs or acute pyelonephritis. Instead, *simple microscopic examination* of a centrifuged urine specimen allows identification of both pyuria and bacteriuria in the sediment. A specimen is examined expeditiously because WBCs deteriorate quickly in urine that has not been appropriately preserved. Standards to define pyuria are inadequate, other than gross counts. Accordingly, the rapid test for leukocyte esterase has become a surrogate for the microscopic WBC count.

Leukocyte esterase testing measures esterase enzyme found in urinary WBCs. If used alone diagnostically, this test has poor sensitivity (Devillé, 2004). Specifically, if specimens are contaminated with vaginal or colonic bacteria or with trichomonads, test results can be falsely positive for uropathogens. Conversely, very concentrated urine or urine with significant proteinuria, ketonuria, or glucosuria will risk false-negative results (Susianti, 2015). The test is most beneficial for its high negative predictive value, which approximates 95 percent (Sawyer, 1984).

Nitrites are produced from nitrates metabolized by bacteria, especially the gram-negative uropathogen family. However, this marker does not identify *Pseudomonas* species or gram-positive pathogens such as staphylococci, streptococci, and enterococci. First morning urine specimens are ideally tested, because more than 4 hours are required for bacteria to convert nitrates to nitrites at levels that are detectable. As a single test, the sensitivity of a positive nitrite test is poor. However, its negative predictive value approximates 90 (Deville, 2004; Marques, 2017).

Together, combined nitrite and leukocyte esterase negative results from a clean-catch, uncontaminated, voided specimen offer a sensitivity of 80 to 90 percent and negative predictive value of 96 percent (Deville, 2004; Marques, 2017; Patel, 2005). Notably, substances that turn the urine red, such as the bladder analgesic phenazopyridine (Pyridium) or ingestion of beets, can lead to false-positive nitrite or leukocyte esterase test results. Vitamin C can cause false-negative readings (Lee, 2017).

Treatment

Treatment options for uncomplicated UTIs are found in (Table 3-14). Notably, during the past two decades, the frequency of infections caused by group B *Streptococcus* and *Klebsiella* species has risen, whereas *E coli* infection rates have diminished. Also, in many locations, sensitivity patterns in *E coli* may warrant avoidance of trimethoprim-sulfamethoxazole as initial empiric treatment. Importantly, for a given patient, FDA

TABLE 3-14. Treatment of Urinary Tract Infection

Infection Category	Antimicrobial Regimen
Uncomplicated cystitis	
Recommended regimens	Nitrofurantoin macrocrystals/monohydrate (Macrobid) 100 mg twice daily for 5–7 days ***or*** Nitrofurantoin macrocrystals (Macrodantin) 100 mg four times daily for 7 days ***or*** Fosfomycin tromethamine (Monurol) single 3-g dose once ***or*** Trimethoprim-sulfamethoxazole DS 160/800 mg (Bactrim DS, Septra DS) twice daily for 3 days[a] ***or*** Trimethoprim-sulfamethoxazole (Bactrim, Septra) 100 mg twice daily for 3 days[a]
Alternative regimens	Specific β-lactams in 3- to 7-day regimens[b] ***or*** Ciprofloxacin (Cipro) 250 mg twice daily for 3 days ***or*** Norfloxacin (Noroxin) 400 mg twice daily for 3 days ***or*** Levofloxacin (Levaquin) 250 mg daily for 3 days
Outpatient pyelonephritis	
Recommended regimens	Ciprofloxacin 500 mg twice daily for 7 days[c] ***or*** Ciprofloxacin 1000 mg daily for 7 days[c] ***or*** Levofloxacin 750 mg daily for 5 days[c] ***or*** Trimethoprim-sulfamethoxazole DS 160/800 mg twice daily for 14 days[c]
Alternative regimens	Specific β-lactams for 10–14 days[b,c]

[a]Not recommended as first line where local resistance rates of *E coli* exceed 20%.
[b]Suitable agents include amoxicillin-clavulanate, cefdinir, cefaclor, cefpodoxime-proxetil.
[c]If the prevalence of fluoroquinolone resistance is thought to exceed 10%, then an initial, single intravenous dose of a long-acting parenteral antimicrobial, such as 1 g of ceftriaxone or a consolidated 24-hr dose of an aminoglycoside, is recommended.
DS = double strength.
From American College of Obstetricians and Gynecologists, 2016; Gupta, 2011, 2017.

(2018) warnings regarding fluoroquinolone-associated peripheral neuropathy, tendonitis, hypoglycemia, and mental confusion should be weighed against clinical drug benefits.

For significant dysuria, up to 2 days of a bladder analgesic such as phenazopyridine (Pyridium), 200 mg orally up to three times daily, may give significant relief. However, gastrointestinal (GI) upset, yellow-orange stained urine and clothing, and hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are potential side effects.

Following treatment, recurrences may develop. In healthy women, recurrent UTI is defined as two or more episodes of symptomatic cystitis within 6 months or three infections within 1 year. Greater oral fluid intake may lower recurrences (Hooton, 2018). For reinfection linked to intercourse, low-dose postcoital antimicrobial therapy with an appropriate agent found in Table 3-14 is usually effective at preventing UTI recurrence. Otherwise, low-dose antimicrobial prophylaxis for 6 to 12 months may be effective but is associated with more side effects. Importantly, evidence of superiority of any particular regimen is lacking (Albert, 2004). In postmenopausal women, vaginal estrogen may be particularly helpful to reduce recurrent UTI (Mody, 2014). Nonantimicrobial prophylactic strategies lack strong evidence but may be considered (Beerepoot, 2016; Jepson, 2012). Of these, proanthocyanidins are considered the important component in cranberry-containing products and inhibit *E coli* adherence to uroepithelium (Gupta, 2007). Last, urologic evaluation of the urinary tract is considered for women with recurrent UTI following modification of known risk factors.

Asymptomatic Bacteriuria

This is defined as isolation of a specified quantitative count of bacteria in an appropriately collected urine specimen obtained from a person without symptoms or signs referable to UTI (Rubin, 1992). In healthy nonpregnant women, the prevalence of this condition rises with age. It is associated with sexual activity and is

more common in diabetics. Moreover, one fourth to one half of elderly women in long-term care facilities have bacteriuria, which is seen primarily in those with chronic neurologic illness and functional impairment.

The Infectious Disease Society of America recommends that nonpregnant premenopausal women not be screened or treated for asymptomatic bacteriuria (Nicolle, 2019). The same is true for diabetic women and for older persons living in the community.

Acute Pyelonephritis

This is defined as infection of the renal parenchyma and pelvicalyceal system. Acute pyelonephritis is typically accompanied by fever and flank or back pain, in addition to symptoms of lower urinary tract infection.

Studies in young healthy women with normal urinary tracts indicate that 7 to 14 days of oral therapy are sufficient for compliant women with mild infection (Gupta, 2011). In one study of more than 50 college women with acute uncomplicated pyelonephritis, resistance to trimethoprim-sulfamethoxazole was seen in 30 percent (Hooton, 1997). Accordingly, for outpatient therapy, an oral fluoroquinolone is recommended treatment unless a pathogen is susceptible to trimethoprim-sulfamethoxazole. Oral fluoroquinolones have excellent bioavailability, tissue penetration, broad-spectrum antibacterial activity, and long half-lives. At initial diagnosis, clinicians may also administer a parenteral dose prior to starting oral therapy (see Table 3-14). This is especially true if the prevalence of fluoroquinolone resistance is thought to exceed 10 percent. Alternatively, if a causative organism is gram-positive, then amoxicillin-clavulanate, cefdinir, cefaclor, or cefpodoxime-proxetil are recommended options (Gupta, 2011).

Hospitalization with intravenous hydration and antibiotic therapy is indicated for women who display significant clinical findings at initial evaluation or who fail to improve with outpatient therapy. Clinical factors that favor admission include vomiting, elevated serum creatinine level, high fever, marked leukocytosis, or other signs of sepsis. Patient factors are advanced age, nursing home residency, abnormal urinary tract anatomy, and severe comorbid health conditions (Kang, 2013; Stalenhoef, 2017). Appropriate initial IV regimens include a fluoroquinolone; an aminoglycoside with or without ampicillin; an extended-spectrum cephalosporin or extended-spectrum penicillin with or without an aminoglycoside; or a carbapenem. The choice among these agents is based on local resistance data and is then tailored based on culture-derived susceptibility.

POSTOPERATIVE INFECTION

Development of a postoperative infection can create significant patient morbidity, most seriously sepsis. Risks for postoperative infection are varied and include both patient- and procedure-related factors. Of these, the degree of wound contamination at the time of surgery plays an important role. Because most gynecologic surgeries are elective, a gynecologist has time and opportunity to decrease microbial inoculum. Thus, BV, trichomoniasis, cervicitis, and urinary tract or respiratory infections ideally are treated and eradicated prior to surgery.

Wound Classification

Surgical wounds are classified according to the degree of bacterial contamination of the operative site at the time of surgery (Mangram, 1999). In general, as the number of operative site bacteria (inoculum) rises, so too does the postoperative infection rate.

Clean wounds are most commonly found in procedures performed for nontraumatic indications, that are without operative site inflammation, and that avoid the respiratory, GI, and genitourinary tracts. No breaks occur in surgical technique. Thus, most laparoscopic and adnexal surgeries are in this category. Postoperative infection rates range from 1 to 5 percent. Prophylactic antibiotics do not lower these rates and are not required.

Clean contaminated wounds are those in which the respiratory, GI, genital, or urinary tract is entered under controlled conditions and without unusual bacterial contamination. Criteria further define that there is no break in surgical technique. Infection rates range from 5 to 15 percent. This group encompasses many gynecologic procedures including total hysterectomy, cervical conization, and dilation and curettage (D & C). Of these, hysterectomy is the gynecologic procedure most frequently followed by surgical site infection. These procedures are usually elective, and only hysterectomy and obstetric D & C require antimicrobial prophylaxis to reduce postoperative infection rates (American College of Obstetricians and Gynecologists, 2018).

Contaminated wounds reflect operations with major breaks in sterile technique or gross GI spillage or incisions in which acute, nonpurulent inflammation is encountered. Infection rates approximate 10 to 25 percent. For this reason, a minimum of 24 hours of perioperative antimicrobial administration is required, and delayed wound closure may be selected. Laparoscopy or laparotomy for acute salpingitis is included in this category.

Dirty or infected wounds are typically old traumatic wounds or those that involve existing clinical infection or perforated viscera. If an abscess is present, wounds are considered dirty. These operative sites are clinically infected at the time of surgery, and subsequent postsurgical infection rates range from 30 to 100 percent. Accordingly, therapeutic antimicrobial therapy is required, and these wounds typically close by secondary intention.

Surgical Site Infection Classification

Criteria for classifying postoperative surgical site infections (SSIs) are provided by the CDC (2019) (Table 3-15). The incisional group is further subdivided into superficial and deep classes (Fig. 3-13). Organ/space infections may develop in spaces or organs other than that opened by the original incision or manipulated during the surgical procedure. Specific sites include the vaginal cuff, urinary tract, and intraabdominal sites. Of note, vaginal cuff infections are generally considered in the organ/space class, presuming they meet at least one of these criteria: purulent drainage from the cuff, abscess at the cuff, or pathogens cultured from fluid or tissue obtained from the cuff. Pelvic infections such as adnexal infection, pelvic abscess, or infected pelvic hematoma also fall into the category of organ/space infection.

TABLE 3-15. Criteria for Defining Surgical Site Infections (SSIs)

Superficial incisional
Involves only skin and subcutaneous tissue of the incision
Develops within 30 days of surgical procedure
Features at least one of the following:
- Purulent drainage from the superficial incision
- Bacteria in culture obtained aseptically from fluid or tissue from the superficial incision
- Incision deliberately opened by surgeon and is culture positive (or not cultured) *and* patient has at least one of the following incisional signs or symptoms:
  - Tenderness or pain
  - Heat or redness
  - Localized swelling
- SSI diagnosis made by surgeon or attending physician

Stitch abscesses are not included in this category
Diagnosis of "cellulitis," by itself, does not meet criterion for SSI

Deep incisional
Involves the deep soft tissues (muscle and fascia) of the incision
Develops within 30 days of surgical procedure
Features at least one of the following:
- Purulent drainage from deep incision of surgical site (but not organ or space component)
- Deep incision that spontaneously dehisces or is deliberately opened by a surgeon and is culture-positive (or not cultured) *and* patient has at least one of the following signs or symptoms:
  - Temperature ≥38°C (100.4°F)
  - Localized pain or tenderness
- Abscess or other infection found by reoperation, histopathology, or radiology

Organ/space
Involves any body part that was opened or manipulated during the operative procedure, excluding the skin incision, fascia, or muscle layers
Develops within 30 days of the surgical procedure
Features at least one of the following:
- Purulent drainage from a drain placed through a stab wound into the organ/space
- Bacteria obtained aseptically from tissue or fluid in that organ/space
- Abscess found by reoperation, histopathology, or radiology

Vaginal cuff infection with purulence, abscess, and/or positive tissue or fluid culture is included in this category

From Centers for Disease Control and Prevention, 2019.

Diagnosis

Physical Findings

Postoperative febrile morbidity is defined as an oral temperature of ≥38°C (≥100.4°F) on two or more occasions, 4 or more hours apart, and 24 or more hours following surgery. Importantly, postoperative febrile morbidity usually is *not* associated with other symptoms or signs of infection and does *not* require antimicrobial therapy. It resolves without antibiotic treatment in the absence of other signs of infection, but detailed evaluation is required to exclude infectious sources.

Evaluation of a patient with postoperative fever requires a thorough history and a careful physical examination to seek surgical and nonsurgical sources. This search is often complemented by laboratory testing and imaging. Nonsurgical causes of fever may include pulmonary complications, IV site phlebitis, and UTI. Investigation of these is found in Chapter 42 (p. 921).

Operative site pain (incisional, lower abdominal, pelvic, and/or lower back) following surgery is normal. However, patients with an operative site infection report worsening pain at the surgery site, and increasing tenderness is present during physical examination. With superficial SSI, pain is superficial and localized to the incision. With pelvic infection, there is deep lower abdominal and/or pelvic pain, and the most common infection sites are the parametria and the vaginal cuff. Pelvic abscess or infected pelvic hematoma is less common, and pain is central.

Abdominal palpation is an integral part of SSI diagnosis. Avoiding the abdominal incision if present, a surgeon slowly, gently, and deeply palpates the lower abdomen over the surgical site following hysterectomy and normally elicits patient discomfort. Tenderness does not mean an acute surgical abdomen or infection. In the immediate postoperative period, this tenderness is expected and resolves quickly within days. Women

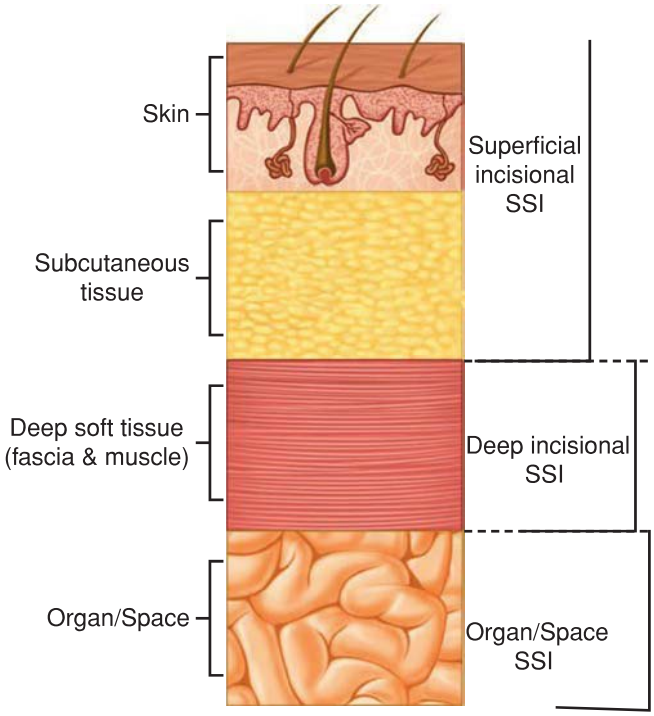

FIGURE 3-13 Anatomy and classification of surgical site infections (SSI).

who develop pelvic cellulitis or cuff cellulitis will have increasing tenderness at gentle depression of the lower abdominal wall over the infected area. Tenderness may be bilateral, but more commonly is more marked on one side. Peritoneal signs are not present. Cellulitis, whether it involves the parametria, adnexa, or vaginal cuff, is not associated with a mass.

In those without worsening lower abdominal pain and tenderness, a bimanual examination is not necessary for asymptomatic temperature elevation. However, with a combination of fever, increasing tenderness, and new-onset pain, a gentle bimanual examination is required to accurately identify the infection site and to exclude or diagnose a mass. Speculum examination usually is not required, and findings from this inspection are similar with or without an existing infection. As is true for routine pelvic examination, most information at bimanual examination is obtained from the vaginal fingers. Bowel function is usually not altered by soft-tissue cellulitis but can be by pelvic abscess or infected pelvic hematoma.

Testing

Pelvic infections following hysterectomy are polymicrobial, and thus, it is difficult to identify true pathogens. Namely, bacteria recovered transvaginally from the pelves of infected and clinically uninfected women are similar. Accordingly, routine transvaginal culturing of women with cuff or pelvic cellulitis does not add useful information. Moreover, a surgeon should not wait for culture results before starting empiric broad-spectrum antibiotic therapy. However, if initial therapy is partially effective or unsuccessful, a culture will more predictably identify pathogen(s) since therapy will have eradicated other species. The antibiotic regimen is then modified, and culture results may direct this change. In contrast, abscess or infected hematoma fluid are cultured since those species are less likely to be vaginal contaminants. The same is true for any fluid or purulent material present in an abdominal incision.

For many postoperative SSIs, imaging is not mandatory. However, if additional anatomic information is needed, transvaginal sonography or CT scanning is most often used, and selection depends on clinical circumstances and suspected etiology. If a mass is appreciated clinically, transvaginal sonography can identify a vaginal cuff abscess or infected cuff hematoma. In those with less specific findings, CT scanning with IV and oral contrast is more likely to aid diagnosis of a broader list of etiologies. Serum creatinine levels are obtained prior to IV contrast, which can be nephrotoxic.

Specific Infections

Vaginal Cuff Cellulitis

Essentially all women develop this infection at the vaginal surgical margin after hysterectomy. Normal healing is characterized by small-vessel engorgement, which results in erythema and heat. Vascular stasis with endothelial leakage follows and results in interstitial edema, which causes induration. This area is tender, microscopic evaluation of a wet prep reveals numerous WBCs, and discharge is seen in the vagina. This process usually subsides, does not require treatment, and does not require reporting as a SSI.

The few women who do require treatment are usually those who present after hospital discharge with mild, but increasing, new-onset lower abdominal pain and have a yellow vaginal discharge (Fig. 3-14). Findings are as above, but the vaginal cuff is tenderer than anticipated at this interval from the initial surgical procedure. Oral antimicrobial therapy with a single broad-spectrum agent is appropriate (Table 3-16). The combination of amoxicillin and clavulanic acid (Augmentin) provides excellent oral broad-spectrum antibiotic coverage. Dual-agent regimens are another option (Lachiewicz, 2015). A patient is then reevaluated in several days to assess therapeutic efficacy. This may be completed by phone or with an examination if necessary.

Pelvic Cellulitis

Commonly following hysterectomy, pelvic cellulitis develops when host humoral and cellular defense mechanisms, combined with preoperative antibiotic prophylaxis, cannot overcome the bacterial inoculum and inflammatory process at the vaginal cuff. This process spreads into the parametria resulting in lower abdominal pain, regional tenderness, and fever, usually during the late second or third postoperative day. Peritoneal signs are absent, bowel and urinary functions are normal, but the patient may note anorexia.

With pelvic cellulitis, hospitalization and treatment with an IV broad-spectrum antibiotic regimen found in Table 3-16 are indicated until a patient is afebrile for 24 to 48 hours. She then may be discharged home. Single-agent therapeutic regimens are as effective as combination-agent regimens. These infections are polymicrobial, and the regimen selected must have coverage for gram-positive and gram-negative aerobic and anaerobic bacteria. Most patients requiring hospitalization for IV antibiotic therapy are discharged with a 5- to 7-day oral antimicrobial prescription.

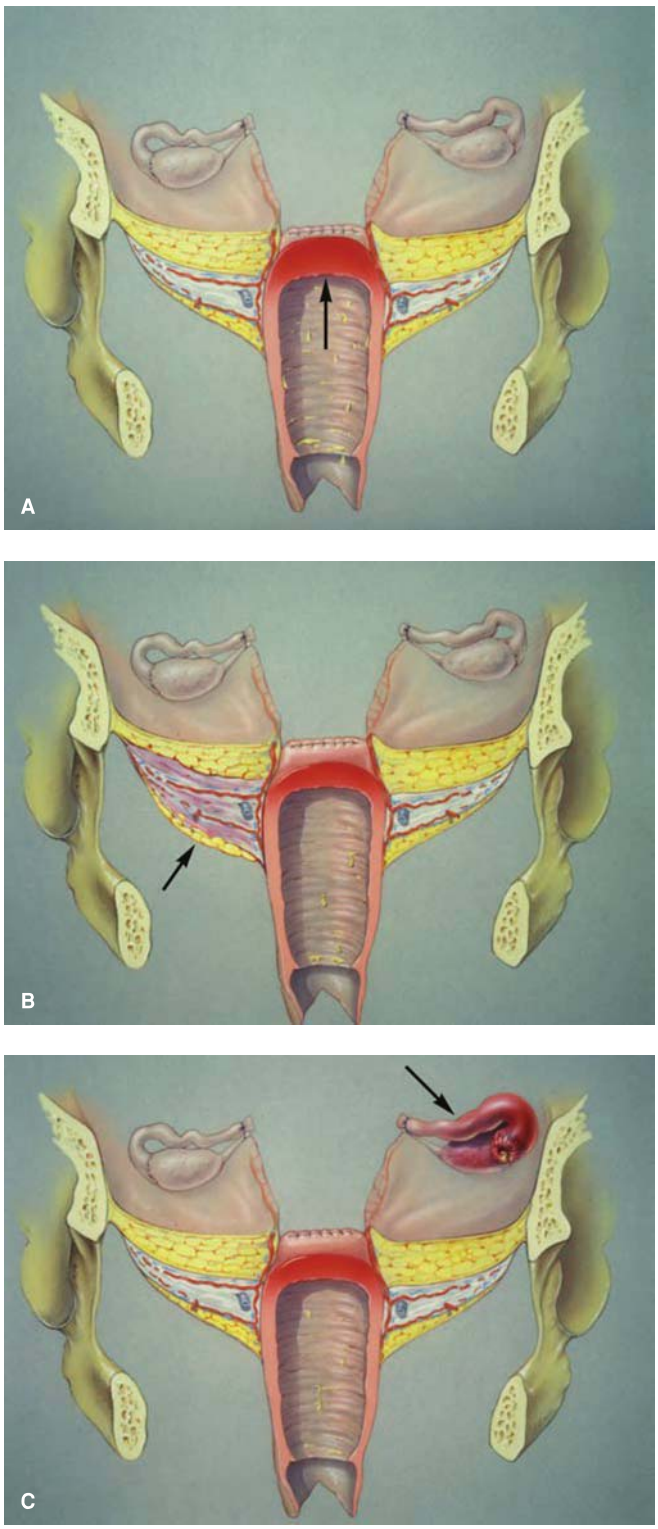

FIGURE 3-14 Organ/space infections. **A.** Vaginal cuff cellulitis. The vaginal surgical margin is edematous, hyperemic, and tender, and there are purulent secretions in the vagina. Parametria and adnexa are normal during gentle bimanual examination. **B.** Pelvic cellulitis in the right parametrium. It is indurated and tender to palpation; no mass is present. **C.** Adnexal infection after hysterectomy. The parametria are normal. Tenderness without a mass is appreciated in the adnexal area.

Of potential IV or oral agents shown in Table 3-16, second-generation cephalosporins have activity against aerobic gram-positive cocci and some gram-negative aerobic and anaerobic bacteria. Third-generation cephalosporins provide gram-positive activity, even greater gram-negative coverage, and some anaerobic effects. With penicillins, the β-lactam ring provides antibacterial activity, which is directed primarily against gram-positive aerobic bacteria. However, pharmacologic manipulation has also created penicillins with added antibacterial spectra that are suitable for pelvic infection. Some bacteria produce an enzyme (β-lactamase) that opens the β-lactam ring and inactivates the drug. Inhibitors of β-lactamase are clavulanic acid, sulbactam, and tazobactam, and these have been combined with several penicillins to enhance their antibacterial spectrum. Additionally, oral probenecid can be administered separately with penicillins. This drug lowers the renal-tubular secretion rate of these antibiotics and is used to raise penicillin or cephalosporin plasma levels.

For gram-negative pathogens, the aminoglycoside gentamicin is primarily selected because of its low cost and clinical efficacy. However, this drug has the potential for nephrotoxicity, and risk factors include older age, renal insufficiency, hypotension, volume depletion, frequent dosing intervals, longer treatment, multiple co-antibiotics, or multisystem disease. For serious pelvic infection, gentamycin is often combined with clindamycin to achieve adequate pathogen coverage. Clindamycin is primarily active against aerobic gram-positive bacteria and most anaerobic bacteria. Its added activity against methicillin-resistant *Staphylococcus aureus* (MRSA) has increased its use in these cases. Metronidazole may be used instead of clindamycin for women with serious postoperative pelvic infections, including pelvic abscess. It is active only against obligate anaerobes and must be combined with agents effective against gram-positive and gram-negative aerobic bacterial species, such as ampicillin and gentamicin.

Adnexal Infection

This infection is uncommon and presents identically to that of pelvic cellulitis. The difference is in the location of tenderness during bimanual pelvic examination. The cuff and parametrial areas are not usually tender, but the adnexa are. This infection may also develop after tubal ligation, surgical therapy for ectopic pregnancy, or other adnexal surgery. Empiric antibiotic regimens are identical to those for pelvic cellulitis (see Table 3-16).

Ovarian Abscess

A rare but life-threatening complication following primarily vaginal hysterectomy is ovarian abscess. Presumably with this infection, surgery is performed in the late proliferative phase of an ovulatory menstrual cycle, and ovaries are in close proximity to the vaginal cuff. As expected, physiologic cuff cellulitis develops normally, but when ovulation occurs, local bacteria gain access to the ovulation site and the corpus luteum. The corpus luteum often is hemorrhagic, and the blood in this functional cyst provides a perfect medium for bacterial growth.

Affected women have an essentially normal postoperative course until approximately 10 days following surgery. At this time, they experience acute unilateral lower abdominal pain, which then involves multiple quadrants. These symptoms reflect rupture of their abscess and abdominal peritonitis. Sepsis commonly follows,

TABLE 3-16. Empiric Antimicrobial Regiments for Postgynecologic Surgery Infections

Regimen	Dose
Single-agent intravenous	
Cephalosporin	
Cefoxitin (Mefoxin)	2 g every 6 hr
Cefotetan (Cefotan)	2 g every 12 hr
Cefotaxime (Claforan)	1–2 g every 8 hr
Penicillin with or without β-lactamase inhibitor	
Piperacillin	4 g every 6 hr
Piperacillin/tazobactam (Zosyn)	3.375 g every 6 hr
Ampicillin/sulbactam (Unasyn)	3 g every 6 hr
Ticarcillin/clavulanate (Timentin)	3.1 g every 4–6 hr
Carbapenems	
Imipenem/cilastatin (Primaxin)	500 mg every 8 hr
Meropenem (Merrem)	500 mg every 8 hr
Ertapenem (Invanz)	1 g once daily
Combination agent intravenous	
Metronidazole (Flagyl)	Loading dose 15 mg/kg; maintenance 7.5 mg/kg every 6 hr
Ampicillin	2 g every 6 hr
Gentamicin	3–5 mg/kg once daily
OR	
Clindamycin	900 mg every 8 hr
Gentamicin	3–5 mg/kg once daily
with or without ampicillin	2 g every 6 hr
Oral agents	
Amoxicillin/clavulanate (Augmentin) alone	875 mg/125 mg twice daily
Metronidazole	500 mg every 12 hr
PLUS	
Trimethoprim-sulfamethoxazole DS 160/800 mg	160/800 every 12hr
Metronidazole	500 mg every 12 hr
PLUS	
Ciprofloxacin (Cipro)	500 mg every 12 hr

and this is a true gynecologic emergency. Immediate exploratory laparotomy is necessary, with IV administration of perioperative broad-spectrum antimicrobials, abscess evacuation, and adnexectomy if easily accessible. At a minimum, necrotic tissues are debrided, which may require oophorectomy. After hospital discharge, oral antibiotics are typically continued for an additional 5 to 7 days, and this is variable depending on the clinical course.

Similarly, women rarely may develop a TOA identical to that seen as an end result of acute PID. This process can be managed medically with IV antimicrobials, and surgery is usually not required unless rupture follows. Depending on size and location, percutaneous drainage may be considered. Broad-spectrum antibiotics are continued until a woman has been afebrile for 48 to 72 hours. Then, IV antibiotics may be replaced by oral agents, which are continued outpatient to complete a 2-week course.

Pelvic Abscess/Infected Pelvic Hematoma

Pelvic abscess not involving an adnexal structure may also uncommonly complicate hysterectomy (Fig. 3-15). This develops from blood, serum, and/or lymph collections following hysterectomy that provide an excellent milieu for the overgrowth of bacteria inoculated into the adjacent tissues during surgery.

An infected surgical pelvic hematoma may present similarly. A classic history in this case is a postoperative hemoglobin level that is significantly lower than predicted by measured intraoperative blood loss, and this reflects postsurgical bleeding. Unlike women who develop tissue cellulitis following surgery and whose early symptom of infection is pain, women with an infected hematoma will have low-grade temperature elevation (>37.8°C) as their early finding. Pain is a late symptom for these women. As prevention, women with an unexplained postoperative hemoglobin drop but no fever are discharged with instructions to monitor their temperature twice daily for approximately 1 week. Temperatures ≥37.8°C typically prompt evaluation.

Signs and symptoms of pelvic abscess or infected hematoma are midline, and a mass is typically discernible centrally. Pelvic abscesses often remain confined to the extraperitoneal space, and a patient does not usually develop peritonitis. Some may develop diarrhea due to the proximity of the rectum, which is usually adjacent to the infected space. Transvaginal sonography

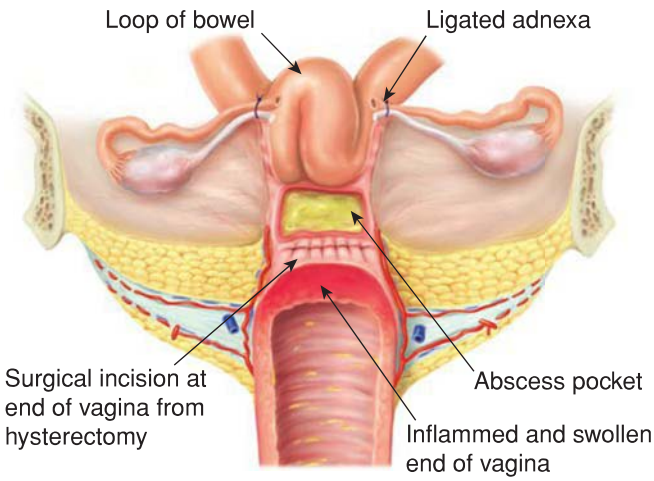

FIGURE 3-15 Pelvic abscess or infected hematoma that is extraperitoneal and cephalad to the vaginal margins.

can accurately characterize the dimensions (Fig. 3-16). In those with a less clear clinical picture, CT scanning may be more effective to exclude other fever etiologies. For both, hospital readmission for broad-spectrum IV antibiotics is usually necessary (see Table 3-16). Additionally, opening the vaginal surgical margin, if possible, to allow drainage will aid treatment. Both these can be drained with sonographic transvaginal guidance or in the operating room.

Combination IV antibiotics are administered until a woman has been afebrile 48 to 72 hours. IV antibiotics may then be replaced by oral agents, which are continued outpatient to complete a 2-week course of therapy, if the abscess or hematoma is not drained. If drained, then oral agents continued for 5 to 7 days following IV agents typically is sufficient.

Abdominal Incision Infection

The superficial and easily accessible location of this infection aids its diagnosis. Abdominal incisions are usually the most uncomfortable following gynecologic surgery, but pain diminishes daily. Erythema and heat are the first physical signs of this infection, which is usually diagnosed on the fourth or fifth postoperative day. A hematoma or seroma may develop in the abdominal wall incision without infection.

Drainage and documentation of an intact fascial incision are basics of abdominal incision infection, hematoma, or seroma treatment. These steps may be performed at the bedside with locally injected lidocaine or in the operative room depending on extent, risk of comorbid fascial dehiscence, and patient tolerance.

If soft-tissue cellulitis is adjacent to the incision, antimicrobial therapy is required. If the initial surgery was a clean procedure, then *Staphylococcus* species predominate. Instead, following clean-contaminated or dirty procedures, isolated organisms commonly include gram-negative bacteria such as *E coli*, *Pseudomonas aeruginosa*, and *Enterobacter* species and gram-positive bacteria, namely, *Staphylococcus* and *Enterococcus* species (Kirby, 2009). Anaerobes are typically not prominent pathogens in these infections but may be present, especially following hysterectomy. Thus, these infections are usually polymicrobial, and antibiotics found in Table 3-16 are suitable.

Subsequent local care with wet-to-dry dressings stimulates fibroblastic proliferation and development of healthy granulation tissue. Moistening the dry dressing prior to its removal will ease removal and decrease patient discomfort. In most cases, wounds are irrigated with normal saline. For some complicated wounds, early wound irrigation with hypochlorous acid (Vashe Wound Solution) is chosen for its antimicrobial properties and skin-neutral pH. Povidone-iodine, iodophor gauze, hydrogen peroxide, and sodium hypochlorite (Dakin solution) are typically avoided once infection has resolved, as they are caustic to healing tissues. Some recommend their use early but follow with normal saline irrigation.

Once uninfected granulation tissue is established, healing may continue by secondary intention. For larger wounds, secondary surgical closure can be considered. Negative-pressure wound therapy provided by vacuum-assisted wound closure devices is available for more serious or larger wounds.

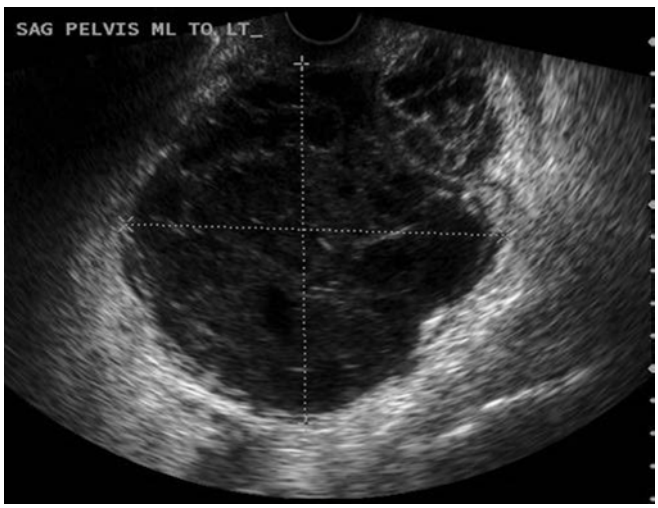

FIGURE 3-16 Transvaginal sonogram of an infected pelvic hematoma following hysterectomy. This 11 × 12 cm collection of blood and clot was drained vaginally in the operative room. (Reproduced with permission from Dr. Elysia Moschos.)

Toxic Shock Syndrome

This condition, caused by an exotoxin (TSS toxin-1) produced by *S aureus*, appears approximately 2 days following surgery or menstruation onset. Menstrual-associated toxic shock syndrome (TSS) rates have diminished following changes in tampon composition and use. For TSS, the vagina or wound must be colonized by a toxigenic staphylococcal strain, and the patient must lack the specific antibody that can block the superantigen.

The classic TSS symptoms include fever, malaise, and diarrhea. If postoperative, signs of wound infection are minimal. A patient has conjunctival and pharyngeal hyperemia without purulence. The tongue is usually reddened, and the skin on the trunk is erythematous but not painful or pruritic. Temperatures are usually above 38.8°C, and orthostatic hypotension or shock may be present. This syndrome results from host cytokines released in response to superantigenic properties of the toxin. The criteria for this diagnosis are presented in Table 3-17.

The wound, if present, is treated like any other wound. It is cultured to confirm presence of *S aureus*. However, results from

TABLE 3-17. Criteria for Diagnosis of Toxic Shock Syndrome

Major criteria
Hypotension
Orthostatic syncope
Systolic BP <90 mm Hg for adults
Diffuse macular erythroderma
Temperature ≥38.9°C
Late skin desquamation, particularly on hands, palms, and soles (1–2 weeks after rash onset)
Minor criteria (organ system involvement)
Gastrointestinal: diarrhea or vomiting
Mucous membranes: oral, pharyngeal, conjunctival, and/or vaginal erythema
Muscular: myalgia or creatinine level greater than twice normal
Renal: BUN and creatinine greater than twice normal or >5 WBCs/hpf in urine, without concurrent UTI
Hematologic: platelet count <100,000 per mm^3
Hepatic: ALT, AST, and/or bilirubin levels greater than twice normal
Central nervous system: altered consciousness without focal localizing signs

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BP = blood pressure; BUN = blood urea nitrogen; hpf = high-power field; UTI = urinary tract infection; WBC = white blood cell.

other cultures (e.g., blood, throat, and cerebrospinal fluid) will be negative. To meet the strict criteria, a woman must have all major and at least three minor criteria. If this is suspected early and therapy is initiated, the complete syndrome may not develop. If obtained, serologies for Rocky Mountain spotted fever, measles, and leptospirosis are negative. Viral infection and group A streptococci also can cause a similar presentation.

While awaiting culture results for selection of specific antistaphylococcal antibiotics, empiric therapy covers both methicillin-susceptible and methicillin-resistant *S aureus.* Vancomycin (15 to 20 mg/kg/dose) can be given every 8 to 12 hours, not exceeding 2 g per dose. Regardless, the hallmark of therapy is entire system support with large volumes of IV fluids and electrolytes to replace massive body fluid losses from diarrhea, capillary leakage, and insensible loss. These patients may develop significant edema and are best managed in an intensive care unit. Even with appropriate management, the death rate can be as high as 5 percent because of subsequent acute respiratory distress syndrome (ARDS), disseminated intravascular coagulopathy (DIC), or hypotension unresponsive to therapy. This syndrome may also follow gynecologic surgical procedures such as D & C, hysterectomy, urethral suspension, and tubal ligation.

Necrotizing Fasciitis

Risk factors for this postoperative incision infection are age older than 50 years, arteriosclerotic heart disease, diabetes mellitus, obesity, debilitating disease, smoking, and previous radiation therapy, all of which are associated with decreased tissue perfusion. In our clinical service, vulvar infection in obese diabetic women is a prominent risk (Fig. 3-17). Only approximately 20 percent

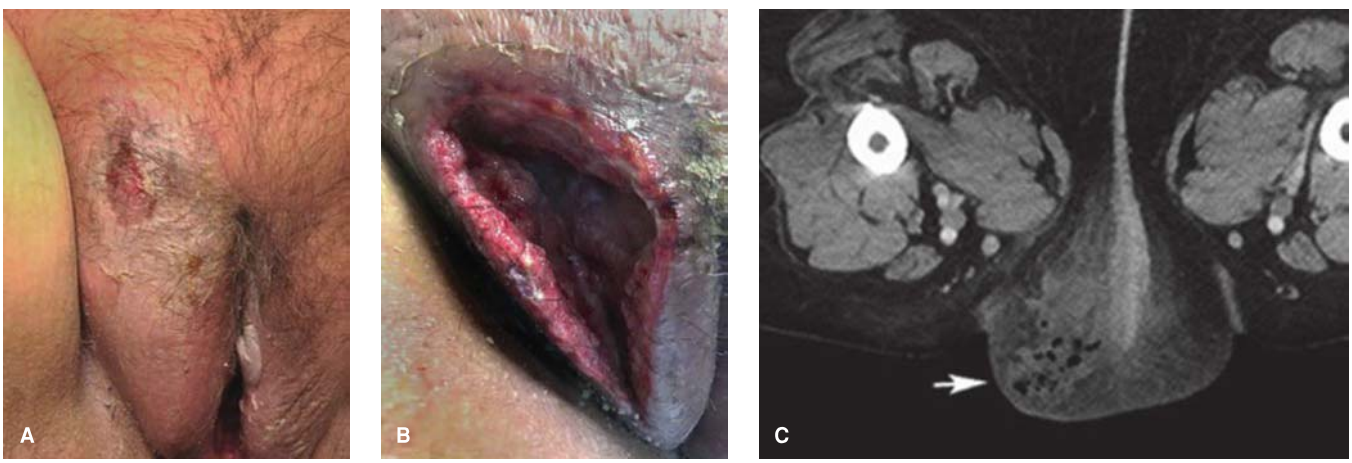

FIGURE 3-17 Vulvar necrotizing fasciitis in an obese, diabetic patient. **A.** Preoperative image of the right labium majus shows mild erythema and moderate edema. A discrete erosion is seen within an area of peeling skin. **B.** After debridement, the extent of tissue destruction is evident. **C.** A diagnostic computed tomography image of this patient shows subcutaneous gas, which is seen as multiple dark round areas within the labium majus (*arrow*).

of cases follow surgery. Bacteria recovered from women with this infection are similar to those recovered from any postoperative gynecologic infection site, namely predominantly *E coli*, *Escherichia faecalis*, *Bacteroides* species, *Peptostreptococcus* species, *S aureus*, and groups A and B hemolytic streptococci.

Although this postoperative superficial incisional infection begins like any other postoperative infection with pain and erythema, its hallmark is subcutaneous and superficial fascial necrosis, manifested by excessive tissue edema in adjacent areas. Blisters or bullae form in tissue that has become avascular and is discolored. Crepitus or induration and edema beyond the region of visible erythema may be present. Tissue destruction is far more extensive than is evident by surface examination, and myonecrosis may be present. The skin will slip over underlying tissue, and if incised, due to the lack of vascularity, there is no bleeding but instead usually a thin, gray transudate. Severe systemic toxicity and fever may develop. In obvious cases, no imaging is needed, and patients are prepared for surgical debridement. In less-clear cases, radiographs or CT scans, if these can be quickly obtained, may add information by revealing gas in affected tissues produced by clostridial species such as *Clostridium perfringens* (see Fig. 3-17) (Ballard, 2018).

Although broad-spectrum antibiotic administration is required, the cornerstone of treatment is prompt recognition and immediate surgical removal of necrotic tissue to a level at which viable bleeding tissue is reached. To achieve this, excision of large tissue volumes is often needed. Although this is potentially disfiguring, postponing surgery while waiting for antimicrobial activity only raises the volume of tissue death. Gynecologists may enlist assistance from a general surgeon or gynecologic oncologist if extensive debridement into the abdominal wall, posterior perineal triangle, buttock, or inner thigh is anticipated. Early fatality rates for patients with this infection approximated 20 percent in the systematic review of 1463 patients by Goh and associates (2014).

Wounds are left open and treated as described earlier (p. 83). Assistance from a general or plastic surgeon for potential grafting is often necessary.

Methicillin-Resistant *Staphylococcus Aureus*

Any of the polymicrobial infections discussed in this section may be complicated by MRSA. To cover MRSA, suitable outpatient oral antibiotics for uncomplicated infection include trimethoprim-sulfamethoxazole DS (160 mg/800 mg) twice daily, clindamycin 300 or 450 mg three times daily, doxycycline or minocycline 100 mg twice daily, or linezolid (Zyvox) 600 mg twice daily. For complicated infections, the Infectious Disease Society of America recommends MRSA coverage with IV vancomycin, IV or oral clindamycin, IV or oral linezolid 600 mg twice daily, IV daptomycin (Cubicin) 4 mg/kg once daily, or IV telavancin (Vibativ) 10 mg/kg once daily (Liu, 2011).

Of these agents, vancomycin is active only against aerobic gram-positive bacteria. It is primarily used by the gynecologist to treat patients with severe allergic reaction to other antibiotics or for MRSA infections. The most significant of vancomycin's side effects is its potential nephrotoxicity, which is enhanced with aminoglycoside therapy. However, the most remarkable is the "red man" syndrome, which is a dermal response to histamine release that creates an erythematous pruritic rash and potentially hypotension. Intravenous administration over 1 hour or administration of an antihistamine may be protective.

TABLE 3-18. Risk Factors for Postoperative Surgical Site Infection

Preoperative
Smoking
Obesity
Poor nutrition
Diabetes mellitus
ASA category ≥3
Immunosuppression
Prior adjacent surgery
Skin shaving at surgical site
Recent skin or soft tissue infection
Perioperative
Emergent procedure
Excessive blood loss
Non–β-lactam prophylaxis
Intraoperative hypothermia
Perioperative hyperglycemia
Laparotomy for abdominal entry
Inadequate antibiotic prophylaxis
Failure to close wound dead space
Higher category wound classification
Prolonged surgical procedure (>3.5 hr)
Non–chlorhexidine-alcohol skin preparation
Foreign body placement (catheter, drain, etc.)
Inadequate irrigation and removal of wound contaminants
Extensive electrosurgical coagulation use or tissue dissection

ASA = American Society of Anesthesiologists.
From Ban, 2017; Lake, 2013; Mahdi, 2014; Steiner, 2017; Uppal, 2016.

Prevention

Because of its greater bacterial exposure, hysterectomy raises the risk of the just described surgical site infections. Other risk factors are listed in Table 3-18.

As prevention, obvious skin or reproductive tract infections are cleared prior to elective surgery. Also, antibiotic prophylaxis immediately before surgery reduces the risk of SSI following abdominal hysterectomy (Ayeleke, 2017). Specifically, SSIs develop in 20 to 30 percent of women after vaginal or abdominal hysterectomy. This rate drops to 15 to 25 percent with preoperative antibiotic prophylaxis. Suitable antibiotics for prophylaxis are listed in Table 39-8 (p. 832). Other preventions are discussed in Chapter 42 (p. 922).

OTHER GYNECOLOGIC INFECTIONS

Vulvar Abscess

These infections develop similarly to other superficial abscesses but have the potential for significant expansion due to the loose areolar subcutaneous tissue in this area. Risk factors

include diabetes, obesity, perineal shaving, and immunosuppression. Common isolates include *Staphylococcus*, group B *Streptococcus*, *Enterococcus* species, *E coli*, and *P mirabilis.* Importantly, Thurman (2008) and Kilpatrick (2010) and their coworkers found MRSA in 40 to 60 percent of cultured vulvar abscesses.

In early stages, surrounding cellulitis may be the most prominent finding and only a small or no abscess is identified. In these cases, sitz baths and oral antibiotics are reasonable. Sizes large than this may be treated with incision and drainage, abscess packing if indicated, and oral antibiotics to treat surrounding cellulitis. For uncomplicated infection, suitable oral agents will be broad-spectrum and will cover MRSA. Trimethoprim-sulfamethoxazole, clindamycin, or doxycycline is a suitable choice, among others. However, for those with a large abscess, immunosuppression, or diabetes, hospitalization and IV antibiotic therapy is often preferred. Again, coverage for MRSA is included in acceptable IV regimens (see Table 3-16).

Large abscesses often require admission for drainage under anesthesia. This provides adequate pain control for abscess drainage and for abscess cavity exploration to disrupt loculated areas of pus. This is illustrated in Chapter 43 (p. 986).

Bartholin Gland Duct Abscess

This infection is managed primarily by drainage (Fig. 3-18). Drainage with either Word catheter placement or marsupialization can typically be completed in an outpatient setting and is described in Chapter 43 (p. 980). Neither technique is clearly superior and depends on clinical circumstance (Kroese, 2017). Antibiotics are often added to treat surrounding tissue cellulitis**.** The most common bacteria isolated from these abscesses include anaerobic *Bacteroides* and *Peptostreptococcus* species and aerobic *E coli*, *S aureus*, *Streptococcus* species, and *E faecalis* (Kessous, 2013; Krissi, 2016). Also, *N gonorrhoeae* and *C trachomatis* may be identified (Bleker, 1990). Thus, polymicrobial coverage is selected, and suitable single-agent oral outpatient therapy includes, among others, trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, or second-generation cephalosporins. In most cases, abscess aerobic cultures are obtained. Depending on patient risks, NAATs for *N gonorrhoeae* and *C trachomatis* and screening for other STDs may be included.

FIGURE 3-18 Left Bartholin gland duct abscess and associated edema of the labium minus.

HUMAN IMMUNODEFICIENCY VIRUS

Pathogenesis

This single-stranded RNA virus causes chronic infection and progressive depletion of specific T lymphocytes known as *CD4 cells*. HIV-1 and HIV-2 are the two distinct viral types. HIV-1 is the most widespread, whereas HIV-2 is found mainly in Africa. The HIV virus is transmitted by either direct inoculation with infected blood or by transepithelial migration across a mucosal barrier. Subsequently, the virus targets CD4 cells by fusing their viral envelope glycoproteins to target cell surface receptors. The viral RNA genome is reverse transcribed into viral DNA, which then integrates into the host genome, leading to further virus replication and transcription. During approximately 10 years without treatment, cycles of CD4 cell infection and depletion coupled with chronic T cell activation and apoptosis eventually lead to late-stage infection (Hazenberg, 2000). Acquired immunodeficiency syndrome (AIDS), also known as stage 3 infection, is the most advanced stage of HIV infection and is diagnosed in those meeting specific criteria. These are a CD4 count <200 cell/μL and AIDS-defining criteria that include *Pneumocystis jirovecii* pneumonia, Kaposi sarcoma, invasive cervical cancer, and others (Selik, 2014).

Screening and Diagnosis

Screening for HIV is recommended at least one time for all women aged 13 to 64 years. Screening is also offered to women seeking evaluation and treatment of STDs or those with other identified risk factors (Centers for Disease Control and Prevention, 2015; American College of Obstetricians and Gynecologists, 2019). STD screening guidelines for nonpregnant, sexually active, asymptomatic women are listed in Table 1-1 (p. 4).

HIV infection may be characterized as acute or chronic, and current diagnostic tests help distinguish the two (Table 3-19). The recommended initial screening test is an FDA-approved, fourth-generation antigen/antibody combination immunoassay that detects both HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen. This antigen is produced before antibody formation in HIV-1 infection (Centers for Disease Control and Prevention, 2014b). No further testing is indicated if the initial screen is nonreactive.

If reactive ("positive"), specimens are tested with an FDA-approved antibody immunoassay that differentiates between HIV-1 and HIV-2 antibodies ("differentiation assay"). In chronic infection, both the initial combination immunoassay and the antibody differentiation assay for the specific HIV type are reactive. In acute infection, specimens may be reactive by fourth-generation combination assay but nonreactive or indeterminate on the differentiation assay. In this case, an FDA-approved HIV-1 NAAT is performed, which identifies early HIV RNA production prior to antibody formation. If the NAAT result is nonreactive ("negative"), the possibility of a false-positive combination immunoassay is considered.

TABLE 3-19. Laboratory Results for Diagnosis of HIV Infection

HIV 1/2 Ag/Ab Combination Immunoassay	HIV 1/2 Differentiation Assay	HIV-1 NAAT	Interpretation
Nonreactive	n/a	n/a	HIV negative
Reactive	HIV-1 positive	n/a	HIV-1 positive
Reactive	HIV positive nontypeable (undifferentiated)	n/a	HIV positive
Reactive	HIV indeterminate	Detected Not detected	Acute HIV-1 positive HIV negative
Reactive	HIV antibody negative	Detected Not detected	Acute HIV-1 positive HIV negative
Reactive	HIV antibody negative or indeterminate	Invalid or not performed	Inconclusive

Ab = antibody; Ag = antigen; HIV = human immunodeficiency virus; n/a = not applicable; NAAT = nucleic acid amplification test.
From Centers for Disease Control and Prevention, 2014c.

If an initial laboratory-based screening antigen/antibody combination assay is not available, an FDA-approved point-of-care or "rapid" test such as Alere Determine HIV 1/2 Ag/Ab Combo test may be used (Centers for Disease Control and Prevention, 2017). However, this single-use test is less sensitive for acute infection than laboratory-based screening tests.

Prevention

Prophylaxis to prevent HIV infection may be provided either post- or preexposure. First, occupational or nonoccupational exposure may warrant postexposure prophylaxis (PEP). The initial evaluation determines the timing of exposure, the HIV status of the source (when possible), the type of infectious fluid(s), and exposure site. Additionally, rapid HIV screening of the exposed person is completed at this first visit. If results are positive, initiation of lifelong antiretroviral therapy (ART), rather than short-term prophylaxis, is warranted. Prompt initiation of PEP should not be delayed in a high-risk exposure and may be continued or stopped after the initial evaluation is complete.

If PEP is elected following a high-risk sexual encounter, prophylaxis with a 28-day course of an approved antiretroviral regimen is initiated within 72 hours (Centers for Disease Control and Prevention, 2016). Guidelines and PEP regimens are discussed in Chapter 1 (p. 22).

Following a high-risk occupational exposure from an HIV-positive individual, an identical 28-day regimen is offered. When the HIV status of the source is unknown, use of PEP is decided on a case-by-case basis with expert consultation (Kuhar, 2013). Exposures across broken skin or mucosal membranes or needle-stick injuries are considered significant. Infectious fluids include blood, semen, vaginal secretions, and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amnionic fluids.

For women with ongoing risk factors for HIV acquisition, ongoing preventive measures are necessary. Risk factors may include: ongoing sexual relationship with an HIV-positive (serodifferent) partner, infrequent condom use with one or more partners who are bisexual males or who inject drugs, and a recent (with the past 6 months) syphilis or gonorrhea diagnosis. If risks are identified, behavioral interventions are initially recommended. Consistent condom use is associated with an 80-percent reduction in transmission among heterosexual couples (Weller, 2002). Additionally, for a woman with a known serodifferent sexual partner, treatment of the partner with ART reduces the transmission risk by more than 90 percent. Achieving viral suppression in the affected partner provides effective prevention (Cohen, 2016).

Daily pharmacologic preexposure prophylaxis (PrEP) with antiretroviral agents is considered in combination with safer sex practices for adults at highest risk and is now a Grade A recommendation for men and women with certain risk factors. Women at highest risk include those with serodifferent partner(s) living with HIV, inconsistent condom use with a partner whose HIV status is unknown and is at high risk (injects drugs or has sex with men and women), and those with a diagnosis of syphilis or gonorrhea within the past 6 months (U.S. Preventive Services Task Force, 2019). Adherence to the medication is essential. The extent to which PrEP contributes to prevention among individuals with a serodifferent partner who is already taking suppressive ART is not known. The CDC offers guidelines for PrEP risk assessment, initial laboratory studies, and ongoing STD screening and monitoring for side effects (Centers for Disease Control and Prevention, 2018b). Additionally, the National Clinicians Consultation Center PrEPline is available at 1-855-448-7737.

Treatment

If HIV infection is diagnosed, referral to an infectious disease specialist for prompt initiation of ART is recommended. Primary therapeutic targets for antiretroviral drugs include the viral reverse transcriptase enzyme, which converts HIV RNA

into DNA inside the host cell; the integrase enzyme, which aids incorporation of HIV DNA into the host genome; and the viral protease enzyme responsible for creating mature viral particles. The initial regimen for a newly diagnosed patient includes two nucleoside reverse transcriptase inhibitors (NRTIs) in combination with a third agent from the integrase inhibitor (INSTI) class, protease inhibitor (PI) class, or non-nucleoside reverse transcriptase inhibitor (NNRTI) class (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2018). When selecting initial ART, medical comorbidities, fertility desires, convenience, and patient motivation are considered. If a patient taking PrEP is diagnosed with HIV infection, PrEP is stopped until a full-dose ART regimen can be initiated (Centers for Disease Control and Prevention, 2018b). All partners with unknown HIV status are referred for testing.

REFERENCES 109

The lower reproductive tract, comprising the vulva, vagina, and cervix, exhibits a wide spectrum of benign and neoplastic diseases. Disorder characteristics often overlap, and thus differentiating normal variants, benign disease, and potentially serious lesions can be challenging. Lower reproductive tract infection is a frequent cause and discussed in Chapter 3 (p. 56), whereas congenital anomalies and preinvasive neoplasia are infrequent and described in Chapters 19 (p. 406) and 29 (p. 620). The benign lesions highlighted in this chapter are common, and mastery of their identification and treatment is essential.

VULVAR LESIONS

Vulvar skin is more permeable than surrounding tissues because of differences in structure, hydration, occlusion, and susceptibility to friction (Farage, 2004). Accordingly, pathology can develop in this area, although frequency estimates are difficult because of patient underreporting and clinician misdiagnosis. Lesions may develop from allergen or irritant exposure, infection, trauma, autoimmunity, or neoplasia. As a result, symptoms may be acute or chronic and include pain, pruritus, dyspareunia, bleeding, and discharge, which all may affect a woman's sense of well-being. Effective therapies are available for most disorders, yet embarrassment and fear may be significant roadblocks for many women.

General Approach

The initial encounter includes reassurance that the patient's complaints will be investigated thoroughly. Women often minimize and may be uncomfortable with describing their symptoms. They may describe protracted histories of assorted diagnoses and treatments by numerous providers and may voice frustration and doubt that relief is possible. Patients are not promised a cure but rather that efforts will be made to control their symptoms. This can require multiple visits, tissue sampling, treatment attempts, and even a multidisciplinary plan. A patient-provider partnership approach to management enhances compliance and satisfaction with care. Patients are often relieved to learn that their complaints and conditions are not unique. Thus, referral to national websites and support groups is usually welcomed.

Diagnosis

History

Scheduling adequate time for the initial evaluation is a wise investment, and detailed patient questionnaires are invaluable. First, symptoms are clarified as to their onset, duration, precise location, and association with vaginal complaints. Vulvar pruritus is often referred to as "vaginal," thus symptom location is ideally clarified. A thorough medical history addresses systemic illnesses, medications, and known allergies. Obstetric, sexual, and psychosocial histories and any potentially provocative events around the time of symptom onset often suggest etiologies. Hygiene and sexual practices are investigated in detail.

Of symptoms, vulvar pruritus is frequent with many dermatoses. Patients may have been previously diagnosed with psoriasis, eczema, or dermatitis at other body sites. Isolated vulvar pruritus may be associated with a new medication. Most often, vulvar pruritus stems from an irritant or allergic contact dermatitis. Common offenders include urine, moist wipes, or washing with strongly scented body soaps or laundry products. Excessive washing and use of wash cloths can result in skin drying and mechanical trauma. Washing often becomes more aggressive with pruritus as patients assume their hygiene is lacking. Any of these practices can create an escalating itch-scratch cycle or exacerbate the symptoms of other preexisting dermatoses. Last, patients frequently use nonprescription remedies for relief of vulvovaginal itching or perceived odor. These products commonly contain multiple known contact allergens, and their use is discouraged (Table 4-1).

TABLE 4-1. Common Vulvar Irritants and Allergens[a]

General Categories	Examples
Antiseptics	Povidone iodine, hexachlorophene
Body fluids	Semen or saliva
Body soaps	Scented soaps, bath salts, shampoos, conditioners
Condoms	Lubricant or spermicide containing
Contraceptive creams, jellies, foams	Nonoxynol-9, lubricants
Dyes	
Emollients	Lanolin, jojoba oil, glycerin
Toilet paper	Colored or scented
Laundry products	Detergents, softeners, dryer sheets
Rubber products	Including latex
Menstrual products	Pad, tampons
Sanitary wipes	Adult or baby wipes
Tea tree oil	
Topical agents:	
Anesthetics	Benzocaine, lidocaine, dibucaine
Antibacterials	Neomycin, bacitracin, polymyxin
Antimycotics	Imidazoles, nystatin
Corticosteroids	
Medications	TCA, 5-FU, podofilox or podophyllin
Vaginal hygiene products	Perfumes, deodorants

5-FU = 5-fluorouracil; TCA = trichloroacetic acid.
[a]Categories arranged alphabetically.
Compiled from American College of Obstetricians and Gynecologists, 2016a; Marren, 1992; Margesson, 2004.

Physical Examination

Examination of the vulva and surrounding skin is completed using adequate lighting, optimal patient positioning, and a magnifying lens. Both focal and generalized skin changes are carefully noted, as neoplasia may arise within a field of generalized dermatosis. Abnormal pigmentation, skin texture, nodularity, or vascularity is evaluated. Touch with a small blunt probe such as a cotton swab defines the anatomic boundaries of generalized symptoms and precisely locates focal complaints (Fig. 4-1). Both photographs and diagrams noting vulvar findings and symptoms can be stored in the medical record to aid treatment assessment over time.

Vaginal complaints or vulvar conditions without obvious etiology typically prompt vaginal examination. Careful inspection may reveal generalized inflammation or atrophy, abnormal discharge, or focal mucosal lesions such as erosions. In these cases, saline preparation of secretions for microscopic evaluation ("wet prep"), vaginal pH testing, potassium hydroxide (KOH) testing, and a standard genital aerobic culture are collected to detect a possible etiology.

A general skin examination, including the oral mucosa and axillae, may suggest the cause of some vulvar conditions. A focused neurologic examination to evaluate lower extremity sensation and strength as well as perineal sensation and tone may help evaluate vulvar dysesthesias.

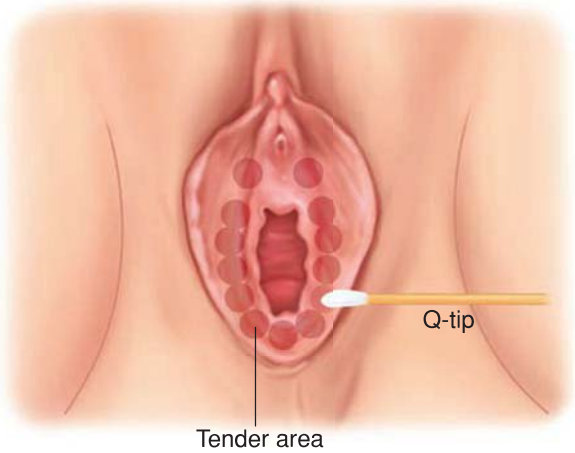

FIGURE 4-1 Pain can be assessed and mapped by systematically touching a cotton-tip applicator to the vulva.

Vulvar Biopsy

Vulvar skin changes are frequently nonspecific and may require biopsy for accurate diagnosis. Biopsy is recommended if the cause of symptoms is not obvious; if focal, hyper-/hypopigmented, or exophytic lesions are present; or if initial empiric treatment fails. During biopsy, ulcerative and erosive lesions are sampled at their edges, whereas indurated areas are biopsied in their thickest region (Mirowski, 2004). Conditions with multiple morphologies may require more than one biopsy for diagnosis.

The steps for vulvar biopsy are shown in Figure 4-2. First, the biopsy site is cleaned with an antimicrobial agent and infiltrated with a 1- or 2-percent lidocaine solution. Biopsy is performed most easily with a Keyes skin punch. Its open, circular blade is designed to remove a shallow disc of tissue when gently pressed against the skin and rotated. Keyes punches are available in various diameters, which range from 2 to 6 mm. Size selection is based on lesion dimensions and on clinical goals of sampling versus excision. Vulvar skin and lesion thicknesses vary, and these are assessed prior to biopsy to avoid over-rotation of or undue pressure on the Keyes punch. Too deep a biopsy will leave a depressed scar. Rotation and pressure should ideally stop when decreased resistance is felt, signaling the dermis has been reached. The tissue disc core is then freed at its base with fine scissors. Larger punch biopsies (4- to 6-mm) may require closure with an absorbable suture or gelfoam.

For raised or pedunculated lesions, fine scissors may be used. Occasionally, a no. 15 blade scalpel is selected for larger focal lesions. Tissue is excised parallel to the natural skin folds, and if needed, the defect is sutured to aid healing and minimize scarring.

An alternative sampling technique is *modified snip excision*. With this, a stitch is begun on one side of the lesion and advanced beneath it to exit on the opposite side. The tissue is gently tented upward, and fine Gradle scissors are used to snip below the stitch to remove an ellipse of tissue. Larger lesions, for which simple closure would create significant incision tension, may be removed as in a wide local excision (Chap. 43, p. 1006).

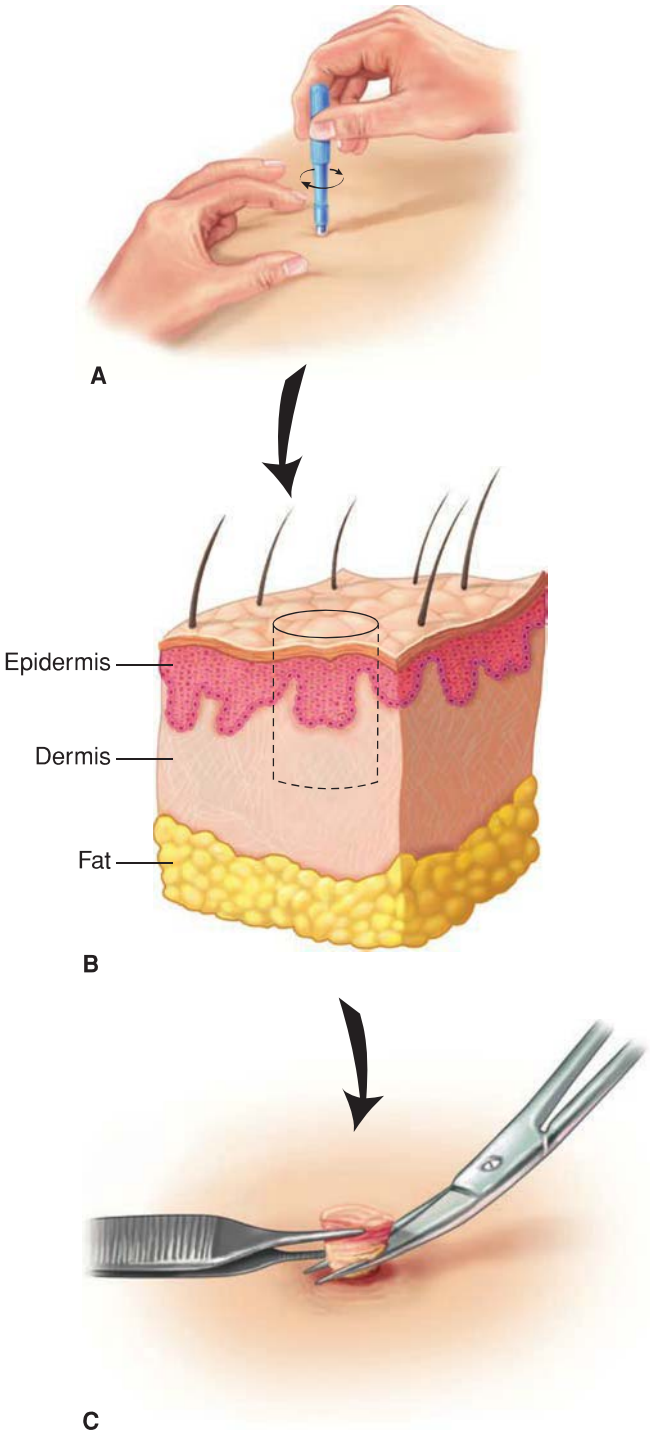

FIGURE 4-2 Vulvar biopsy steps. **A.** A Keyes punch biopsy is placed against the biopsy site. Gentle downward pressure is exerted as the punch is rotated. **B.** A core biopsy is created that extends through the epidermis and into the dermis. **C.** The tip of a fine needle is used to elevate the core, while fine scissors incise its base.

Following biopsy, direct pressure with topical aluminum chloride, Monsel paste, or silver nitrate stick can control bleeding. The last two may permanently discolor the skin and confuse subsequent examinations. If needed, simple interrupted stitches using a fine, rapidly absorbable suture provide hemostasis and edge approximation. Nonnarcotic oral analgesics generally relieve postbiopsy discomfort, if present.

VULVAR DERMATOSES

Lichen Simplex Chronicus

The International Society for the Study of Vulvovaginal Disease (ISSVD) provides classification systems for vulvar abnormalities (Lynch, 2007, 2012). Of these, lichen simplex chronicus originates from an itch-scratch cycle that leads to chronic trauma from rubbing and scratching (Lynch, 2004). The skin responds by thickening with exaggerated gray, leathery-appearing skin markings termed *lichenification*. Skin changes are usually bilateral and symmetric and may extend beyond the labia majora. Intense vulvar pruritus causes functional and psychologic distress, and sleep is often disrupted. This is often the end stage of other dermatologic conditions that include lichen sclerosus, atopic dermatitis, or psoriasis. Other irritants such as tight clothing, heat, sweating, or products listed in Table 4-1 may cause this condition (Virgili, 2003). Finally, neurologic or psychiatric disorders may results in repetitive scratching and are ideally addressed (Guerrero, 2015). A detailed history typically leads to the diagnosis.

Treatment involves halting the itch-scratch cycle. First, provocative stimuli are eliminated, and topical corticosteroid ointments help reduce inflammation. In addition, lubricants, such as plain petrolatum or vegetable oil, and cool sitz baths help to restore the skin's barrier function. Oral antihistamine use, trimmed fingernails, and cotton gloves worn at night can help decrease scratching during sleep. Depending on the degree of inflammation, treatment from 4 to 12 weeks is needed to alleviate symptoms. Histology classically shows thickening of both the epidermis (acanthosis) and the stratum corneum (hyperkeratosis). This condition often reoccurs, thus education and maintenance therapy with bland emollients is important. In refractory cases, questions regarding new irritant exposures and a trial of higher potency corticosteroid are reasonable. If symptoms fail to resolve, biopsy is indicated to exclude other pathology.

Lichen Sclerosus

This classically presents in postmenopausal women and prepubertal girls, although cases are found less often in premenopausal women and men (Fig. 15-8, p. 325). In one referral dermatologic clinic, lichen sclerosus was found in 1:300 to 1:1000 patients with a tendency toward whites (Goldstein, 2005a). Others estimate an incidence of childhood lichen sclerosus to be 1 in 900 (Powell, 2001).

The cause of lichen sclerosus remains unknown, although infectious, hormonal, genetic, and autoimmune etiologies have been suggested. Approximately 20 to 30 percent of patients with lichen sclerosus have other autoimmune disorders, such as Graves disease, types 1 and 2 diabetes mellitus, systemic lupus erythematosus, and achlorhydria, with or without pernicious anemia (Bor, 1969; Kahana, 1985; Poskitt, 1993). Accordingly, concurrent testing for these is indicated if other suggestive findings are present.

Diagnosis

Although sometimes asymptomatic, most individuals with lichen sclerosus complain of anogenital symptoms that often

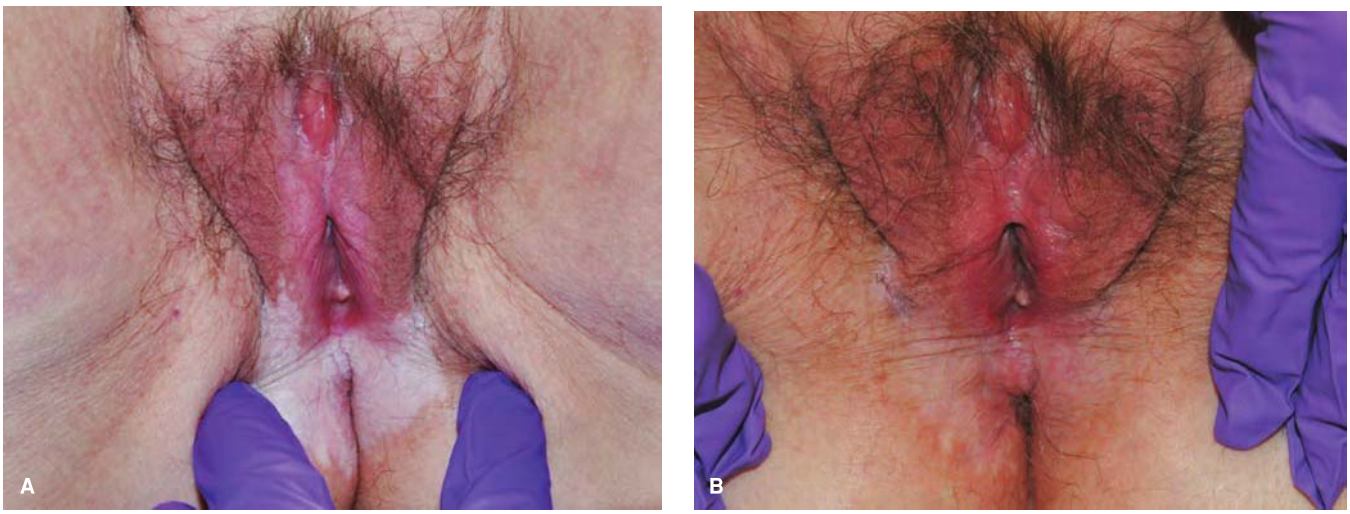

FIGURE 4-3 Vulvar lichen sclerosus. **A.** Note the thin and pale vulvar skin, loss of labia minora architecture, labia minora fusion beneath the clitoris, and hourglass distribution around vulva and anus. **B.** Skin fullness and texture improved following several weeks of topical corticosteroid ointment. (Reproduced with permission from Dr. David D. Rahn.)

worsen at night. Inflammation of local terminal nerve fibers is suspected. Pruritus-induced scratching creates a repetitive cycle that may lead to excoriations and vulvar skin thickening. Late symptoms can include burning and dyspareunia due to vulvar skin fragility and structural changes.

Perianal involvement is frequently seen. The typical white, atrophic papules may coalesce into porcelain-white plaques that distort normal vulvar anatomy. As a result, labia minora regression, clitoral concealment, urethral obstruction, and introital stenosis can develop. The skin generally appears thinned and crinkled. Over time, involvement may extend to the perineum and anus to form a "figure-eight" or "hourglass" shape (Fig. 4-3) (American College of Obstetricians and Gynecologists, 2016a). Thickened white plaques, areas of erythema, or nodularity should prompt biopsy to exclude preinvasive and malignant lesions. This characteristic clinical picture and histologic findings typically confirm the diagnosis. In long-standing cases, histologic findings may be nonspecific, and clinical suspicion will guide treatment.

Treatment and Surveillance

Curative therapies are not available for lichen sclerosus. Thus, treatment goals are symptom control and prevention of anatomic distortion. Despite its classification as a nonneoplastic dermatosis, patients with lichen sclerosus have a higher risk of vulvar malignancy. Malignant transformation within lichen sclerosus develops in 5 percent of patients in whom histologic cellular atypia may precede a diagnosis of invasive squamous cell carcinoma. Accordingly, lifetime surveillance of women with lichen sclerosus every 6 to 12 months is suggested (Lee, 2015). Persistently symptomatic, new, or changing lesions are biopsied (American College of Obstetricians and Gynecologists, 2016a).

As with all vulvar disorders, hygiene recommendations focus on minimizing chemical and mechanical skin irritation (Table 4-2). The chronicity of lichen sclerosus and lack of cure elicits an array of emotions. Support groups dedicated to this condition, such as that found at www.lichensclerosus.org, offer needed psychologic support.

Corticosteroids. First-line therapy is an ultrapotent topical corticosteroid preparation, which offers effective antiinflammatory, antipruritic, and vasoconstrictive properties. Examples are 0.05-percent clobetasol propionate, 0.05-percent halobetasol propionate, or 0.05-percent betamethasone dipropionate ointment. Ointment formulations are preferred to creams due to their protective and less irritating properties (Table 4-3). Common side effects such as striae and telangiectasias can develop if medication is used incorrectly. Theoretic adrenocorticosuppression and iatrogenic Cushing syndrome may be risks if topical corticosteroid preparations are used in large doses for extended periods.

Treatment initiation within 2 years of symptom onset usually prevents significant scarring, but no treatment scheme is universally accepted for topical corticosteroid use. Current recommendations are once- to twice-daily treatment for up

TABLE 4-2. Vulvar Hygiene Recommendations

Avoid using gels, scented bath products, moisturizing wipes, and soaps, as they may contain irritants
Avoid douching
Use aqueous creams to clean the vulva and thoroughly rinse with tepid water
Avoid using a harsh washcloth to clean the vulva
After bathing, sparingly apply an emollient, such as plain petrolatum, to moist vulva epithelium
Dab the vulva gently to dry
Avoid wearing tight-fitting pants
Select white cotton underwear
Avoid washing undergarments in commercial washing detergents. Wash and rinse these items separately. Consider using a multirinse process with cold water to remove any remaining detergent residue
Consider wearing skirts and no underwear at home and at night to avoid friction and aid drying

TABLE 4-3. Topical Medication Guide

Steroid Class Potency	Generic Name	Brand Names (available forms)
Ultrapotent	Betamethasone dipropionate augmented 0.05% Clobetasol propionate 0.05% Diflorasone 0.05% Halobetasol propionate 0.05%	Diprolene (oint., gel) Temovate (cream, gel, oint.) Psorcon (cream, oint.) Ultravate (cream, oint.)

Low	Alclometasone dipropionate 0.05% Betamethasone valerate 0.01% Fluocinolone acetonide 0.01% Hydrocortisone 1%, 2.5%	Aclovate (cream, oint.) Valisone (cream, lotion) Synalar (solution) Generic OTC versions 1% or 2.5% (cream, oint., lotion)

Oint. = ointment; OTC = over the counter.

to three months depending on disease thickness. Studies now show that maintenance therapy of three times weekly, even in asymptomatic patients, significantly decreases the development of squamous cell carcinoma (Lee, 2015). During initial treatment, some patients may also require oral antihistamines, particularly at night, to control itching.

Corticosteroids can also be injected into affected areas, a treatment offered by specialty clinics familiar with techniques and potential complications. One study of eight patients evaluated the efficacy of once-monthly intralesional infiltration of 25 to 30 mg of triamcinolone hexacetonide for a total of 3 months. Severity scores declined in all categories including symptoms, gross appearance, and histopathologic findings (Mazdisnian, 1999).

Other Topical Treatments. *Estrogen cream* is not a primary therapy for lichen sclerosus. However, its addition is indicated for menopausal atrophy, labial fusion, and dyspareunia. Testosterone ointment has failed to show efficacy in trials and is no longer recommended (Bornstein, 1998; Sideri, 1994). *Retinoids* historically used in the past for lichen sclerosus have fallen out of favor given their epithelial irritation side effects. *Topical calcineurin inhibitors* such as tacrolimus (Protopic) and pimecrolimus (Elidel) have antiinflammatory and immunomodulating effects. These are indicated for moderate to severe eczema and have been evaluated for lichen sclerosus (Goldstein, 2011; Hengge, 2006). However, one double-blind, randomized study found topical clobetasol propionate to be more effective in treating vulvar lichen sclerosus than topical tacrolimus (Funaro, 2014). In the face of Food and Drug Administration (FDA) (2015) concerns regarding its link to various cancers, clinicians ideally exercise caution when prescribing tacrolimus for extended periods.

Last, *phototherapy* after pretreatment using 5-aminolevulinic acid was investigated in one small series of 12 postmenopausal women with advanced lichen sclerosus. Significant reductions in patient symptoms and short-term improvement for up to 9 months were noted (Hillemanns, 1999). Fractionated carbon dioxide (CO_2) laser has been combined with long-term topical corticosteroids for severe hypertrophic lichen sclerosus (Lee, 2016). However, it is not FDA approved for treatment of lichen sclerosus, and additional studies are needed.

Surgery. Surgical intervention is reserved for significant sequelae and not for primary treatment of uncomplicated lichen sclerosus. For introital stenosis, Rouzier and coworkers (2002)

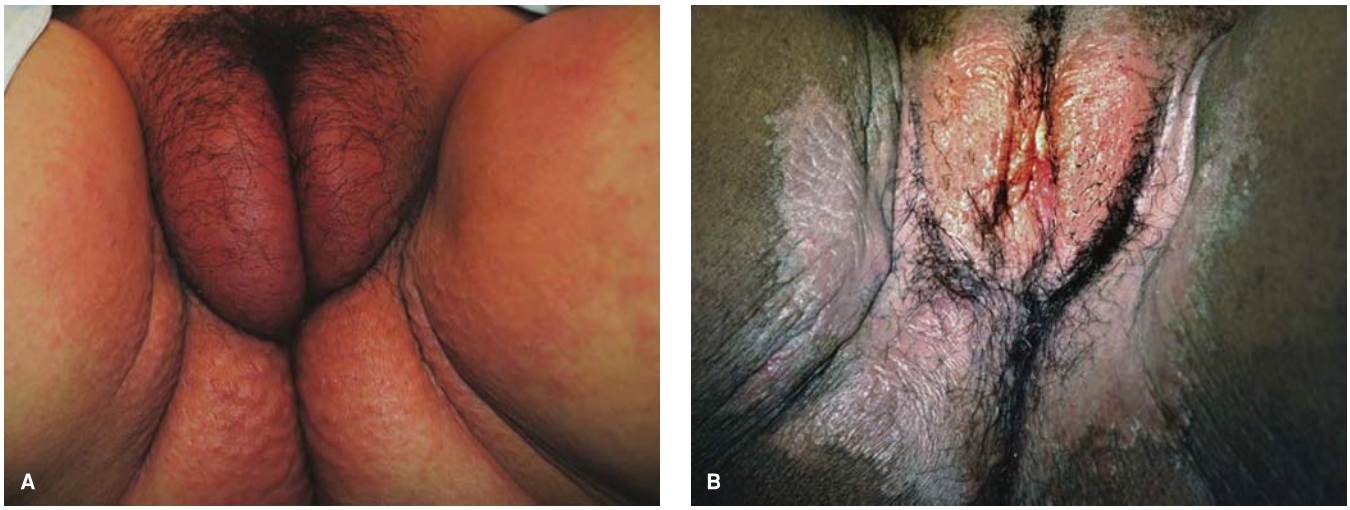

FIGURE 4-4 Vulvar contact dermatitis. **A.** Reaction to povidone-iodine solution. Contact sites show symmetric erythema and edema on the vulva, inner thighs, and buttocks. (Reproduced with permission from Dr. Alicia N. Kiszka.) **B.** Chronic dermatitis creates thick, leathery skin.

described marked improvements in dyspareunia and quality of sexual intercourse if perineoplasty was performed (Chap. 43, p. 988). Vaginal dilation and corticosteroids are recommended following most surgical corrections of introital stenosis. For symptomatic clitoral adhesions, surgical dissection can be used to free the hood from the glans. Reagglutination can be averted using nightly application of ultrapotent topical corticosteroid ointment. After the surgical site is healed, clobetasol application is decreased to twice weekly (Goldstein, 2007).

Inflammatory Dermatoses

Contact Dermatitis

A primary irritant or allergen creates vulvar skin inflammation, termed *contact dermatitis* (Fig. 4-4). This condition is common and affects all ages. In unexplained cases of vulvar pruritus and inflammation, irritant contact dermatitis is diagnosed in up to 54 percent of patients (Fischer, 1996).

Irritant contact dermatitis classically presents as immediate burning and stinging upon exposure to an offending agent. In contrast, patients with *allergic contact dermatitis* experience a delayed onset and an intermittent course of pruritus and localized erythema, edema, and vesicles or bullae (Margesson, 2004). A detailed history will help distinguish between the two and help identify the irritant (see Table 4-1).

With allergic contact dermatitis, patch testing may aid in identifying responsible allergen(s). Associated conditions, such as candidiasis, psoriasis, seborrheic dermatitis, and squamous cell carcinoma, can be excluded through appropriate use of cultures and biopsy. Classic histologic features are mild spongiosis, epidermal cell necrosis, and neutrophilic infiltrate of the epidermis.

Treatments for both entities involve elimination of the offending agent(s), restoration of the natural protective skin barrier, inflammation reduction, and scratch cessation (Table 4-4) (Farage, 2004; Margesson, 2004).

Intertrigo

Friction between moist skin surfaces produces this chronic condition. Found most often in labiocrural folds, intertrigo can also develop in the inguinal or intergluteal regions or below a lower abdominal panniculus. Superimposed bacterial and fungal infections may complicate the condition.

If untreated, the initial erythematous phase can progress to intense inflammation with erosions, exudate, fissuring, maceration, and crusting (Mistiaen, 2004). Symptoms typically include burning and itching. With long-standing intertrigo, hyperpigmentation and verrucous changes can develop.

Treatment entails the use of drying agents such as antifungal powders or zinc oxide paste and application of mild topical corticosteroids for inflammation. If skin changes do not respond, then seborrheic dermatitis, psoriasis, atopic dermatitis, pemphigus vegetans, or even scabies are considered. If the area is superinfected with bacteria or yeast, directed therapy is provided (Chap. 3, p. 65).

TABLE 4-4. Treatment of Vulvar Contact Dermatitis

1. Stop offending agents and/or practices
2. Correct vulvar skin barrier function
   a. Sitz bath twice daily with plain water
   b. Application of plain petrolatum
3. Treat any underlying infection
   a. Oral antifungal therapy
   b. Oral antibiotic administration
4. Reduce inflammation
   a. Topical corticosteroids twice daily for 1–3 weeks
      i. 0.05% clobetasol propionate ointment
      ii. 0.1% triamcinolone ointment
   b. Systemic corticosteroids for severe irritation
5. Break the itch-scratch cycle
   a. Cool packs (avoid ice packs, which may injure skin)
   b. Plain, cold yogurt on a sanitary napkin for 5–10 minutes
   c. Consider an SSRI (sertraline [Zoloft] 50–100 mg) or an antihistamine (hydroxyzine [Vistaril] 25–100 mg)

SSRI = selective serotonin-reuptake inhibitor.

To prevent recurrences, obese patients are encouraged to lose weight. Other preventions include light-weight, loose-fitting clothing made of natural fibers, improved skin ventilation, and thorough drying between skin folds after bathing (Janniger, 2005).

Atopic Dermatitis

This classically presents in the first 5 years of life as a severe pruritic eruption. Scaly patches with fissuring are evident. Atopic dermatitis follows a chronic, relapsing course, and affected individuals may later develop allergic rhinitis and asthma (Spergel, 2003).

Topical corticosteroids and immunomodulators, such as tacrolimus, can control flares (Leung, 2004). For dry skin, moisturizing with emollients can offer relief.

Psoriasis

Approximately 1 to 2 percent of the United States' population is affected by psoriasis (Gelfand, 2005). Psoriasis is a T-cell–mediated autoimmune process in which proinflammatory cytokines induce keratinocyte and endothelial cell proliferation. Typically, thick, red plaques covered with silvery scales are found on extensor limb surfaces. Occasionally, lesions involve the mons pubis or labia. Here, vulvar plaques are well defined and dull red and often lack the characteristic silver scale of psoriasis (Fig. 4-5). Psoriasis can be exacerbated by nervous stress and menses, with remissions experienced during summer months and pregnancy. Pruritus may be minimal or absent, and this condition is often diagnosed by skin findings alone.

For treatment, topical corticosteroids are widely used because of their rapid efficacy. High-potency corticosteroids are applied to affected areas twice daily for 2 to 4 weeks and then reduced to weekly applications. Diminishing response and skin atrophy are potential disadvantages of long-term corticosteroid use, and recalcitrant cases are best managed by a dermatologist. Vitamin D analogues, such as calcipotriene (Dovonex), are similar in efficacy to potent corticosteroids and avoid skin atrophy. However, these are frequently associated with local irritation (Smith, 2006). Phototherapy offers short-term relief, but long-term treatment plans require a multidisciplinary team (Griffiths, 2000). For moderate to severe psoriasis, several FDA-approved immunomodulating biologic agents are available such as infliximab, adalimumab, etanercept, and ustekinumab (Smith, 2009).

Lichen Planus

This uncommon disease involves both cutaneous and mucosal surfaces and affects genders equally between ages 30 and 60 years (Mann, 1991). Genital lichen planus affects 1 to 2 percent of the general United States' population (Zendels, 2015).

Although not completely understood, T-cell–mediated autoimmunity directed against basal keratinocytes is thought to underlie its pathogenesis (Goldstein, 2005b). Lichen planus may be drug-induced, and nonsteroidal antiinflammatory drugs, β-blocking agents, methyldopa, penicillamine, and quinine drugs have been implicated. Vulvar lichen planus can present as one of three variants: (1) erosive, (2) papulosquamous, or (3) hypertrophic. Of these, erosive lichen planus is the most common vulvovaginal form and the most difficult variant to treat.

FIGURE 4-5 Psoriasis. Raised plaques are seen on the vulva. (Reproduced with permission from Dr. Saly Thomas.)

Diagnosis. Table 4-5 summarizes the most common imitations of lichen planus. Women typically complain of chronic vaginal discharge with intense vulvovaginal pruritus, burning pain, dyspareunia, and postcoital bleeding. On inspection, papules classically are brightly erythematous or violaceous, flat-topped, shiny polygons. These are most commonly found on the trunk, buccal mucosa, or extremity flexor surfaces (Goldstein, 2005b; Zellis, 1996). Lacy, white striations (Wickham striae) are frequently found in conjunction with the papules and may also be present on the buccal mucosa (Fig. 4-6). In the posterior vestibule, well-defined erosions can extend to the labia, resulting in agglutination. With speculum insertion, vulvar skin and vaginal mucosa may bleed easily, and a copious vaginal discharge may be present. Vaginal erosions can produce adhesions and synechiae, which may lead to vaginal obliteration.

TABLE 4-5. Differential Diagnosis of Lichen Planus

Class of Lichen Planus	Mimicking Condition
Erosive lichen planus	Lichen sclerosus Pemphigoid vulgaris Mucous membrane pemphigoid Behçet disease Plasma cell vulvitis Erythema multiforme major Stephen-Johnson syndrome Desquamative inflammatory vaginitis
Papulosquamous lichen planus	Molluscum contagiosum Genital warts
Hypertrophic lichen planus	Squamous cell carcinoma

Compiled from Goldstein, 2005b; Kaufman, 1974; Moyal-Barracco, 2004.

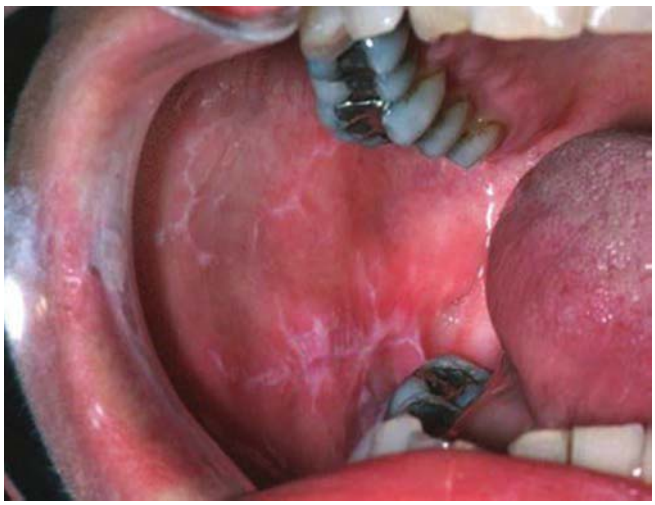

FIGURE 4-6 Oral lichen planus. Mucosal lesions manifest commonly as lacy, white striations (Wickham striae), although white papules or plaques, erosions, or blisters may also be seen. Oral lesions predominantly affect the buccal mucosa, tongue, and gingiva. (Reproduced with permission from Dr. Edward Ellis.)

Women with suspected lichen planus require a thorough dermatologic survey looking for extragenital lesions. Nearly one quarter of women with oral lesions will have vulvovaginal involvement, and most with erosive vulvovaginal lichen planus have oral involvement (Cooper, 2006). Diagnosis is confirmed by biopsy of the linear, white border at the junction of normal skin and erosive disease.

Vulvar Lichen Planus Treatment. Pharmacotherapy remains the first-line treatment for this condition. Additionally, vulvar hygiene, discontinuing any medications associated with lichenoid changes, and psychologic support are instituted.

Erosive vulvar lichen planus is treated initially with ultrapotent topical corticosteroid ointments. One regimen is 0.05-percent clobetasol propionate applied daily for up to 3 months and then slowly tapered. Refractory cases are common, and nearly 40 percent of patients will need more than one treatment to control disease progression (Bradford, 2013).

Vaginal Lichen Planus Treatment. Commonly prescribed to treat hemorrhoids, corticosteroid suppositories containing 25 mg of hydrocortisone and used vaginally can be helpful. In one regimen, these are inserted twice daily, and then the dosage is tapered for symptom remission maintenance (Anderson, 2002). For poorly responding patients, compounding pharmacies can provide a 100-mg hydrocortisone suppository. Potent corticosteroids are prescribed judiciously, as systemic absorption may lead to adrenocorticosuppression (Moyal-Barracco, 2004). Combining local corticosteroid therapy with vaginal dilator use may help restore coital function in patients with moderate vaginal synechiae.

If topical medications fail for either vulvar or vaginal lichen planus, systemic treatment with prednisone 40 to 60 mg daily for up to 4 weeks may modulate symptoms (Moyal-Barracco, 2004). Although no alternative systemic medications have been fully studied, methotrexate, hydroxychloroquine, and mycophenolate mofetil administered by providers familiar with their use are effective within a multidisciplinary approach (Eisen, 1993; Frieling, 2003; Lundqvist, 2002). Surgical adhesiolysis is a last resort. In general, vulvovaginal lichen planus is a chronic, recurrent disease for which symptomatic improvement is possible, but complete control is unlikely.

Hidradenitis Suppurativa

This chronic disease is manifested by recurrent papular inflammatory lesions that may lead to abscess, fistula formation, and scarring predominantly in apocrine gland–bearing skin (Fig. 4-7). In order of frequency, affected areas include the axillae; inguinal, perianal, and perineal skin; inframammary regions; and retroauricular skin. Chronic inflammation obstructs skin follicles, and subcutaneous abscess formation, skin thickening, and deformity follows. Abscesses typically form sinus tracts, and the resulting disfigurement and chronic purulent drainage can be devastating physically, emotionally, and sexually. Described

FIGURE 4-7 Hidradenitis suppurativa. **A.** This case of Hurley stage II shows several distinct fistulous tracts that end in raised nodules of granulation tissue (Reproduced with permission from Dr. David Rogers). **B.** In this Hurley stage III case, multiple and connecting tracts drain purulent fluid and create marked disfiguration.

by the Hurley classification, stage I has transient inflammatory lesions without scarring. Stage II shows single or widely spaced lesions with sinus tracts and scarring. Diffuse involvement and multiple connecting tracts between abscesses characterize stage III (Hurley, 1989).

The etiology of hidradenitis suppurativa is unknown. More than one quarter of patients will report a family history of disease, and an autosomal dominant inheritance pattern is hypothesized (der Werth, 2000). Although Mortimer and colleagues (1986) found higher plasma concentrations of androgens in women with hidradenitis suppurativa, others have not replicated this finding (Barth, 1996).

Treatment of early presenting cases includes local hygiene, weight reduction in obese patients, topical or oral antibiotics, and warm compresses. For mild episodic disease as needed, an initial treatment of topical 1-percent clindamycin solution applied twice daily plus benzoyl-peroxide wash three times weekly is often effective. Local cysts may be treated with injections of triamcinolone acetonide rather than incision and drainage (Riis, 2016). Used individually, appropriate long-term oral antibiotics with antiinflammatory effects include: tetracycline, 500 mg twice daily; erythromycin, 500 mg twice daily; doxycycline, 100 mg twice daily; or minocycline, 100 mg twice daily. A 10-week course of clindamycin, 300 mg twice daily, plus rifampicin, 600 mg twice daily, also has shown efficacy (Gener, 2009).

As reviewed by Rhode and associates (2008), other treatment modalities offer varying efficacies. These include systemic cyproterone acetate (an antiandrogen available in Europe), corticosteroids, isotretinoin, cyclosporine, and infliximab. In their evidence-based review, Alhusayen and Shear (2012) suggest antibiotics or agents targeting tumor necrosis factor alpha (TNF-α) are effective for hidradenitis. Nonmedical therapies include laser and phototherapy. Severe, refractory cases may require surgical excision that often involves extensive resection of the vulva and surrounding areas (Rhode, 2008). Hu and Haefner (2018) have published their successful treatment of severe disease after vulvectomy with skin grafting and vacuum-assisted closure. Unfortunately, postoperative local recurrences can develop.

Aphthous Ulcers

Nearly 25 percent of women in the second and third decade of life will experience these self-limited mucosal lesions. Classically found on nonkeratinized oral mucosa, aphthous ulcers may also develop on vulvovaginal surfaces. Lesions are painful and can recur every few months. Distinguishing an aphthous ulcer from genital herpes may require herpes simplex virus (HSV) polymerase chain reaction (PCR) testing and/or targeted biopsies. Histologically, aphthous ulcers show a mononuclear infiltrate with a fibrin coating. Although the etiology is unknown, immune-mediated epithelial cell damage is one theory (Rogers, 1997). Other described triggers include stress, trauma, infection, hormonal fluctuation, and nutritional deficiencies of vitamin B_{12}, folate, iron, or zinc (Torgerson, 2006). The ulcers are normally self-limited, but persistent lesions can lead to painful scarring (Rogers, 2003). If large mutilating aphthae develop in an adolescent girl, nonsexual acute genital ulceration (NAGU) is suspected. Aphthae may also be the first cutaneous manifestation of systemic diseases, described next.

No cure is available, yet treatment goals include basic vulvar skin hygiene and pain management with topical analgesics such as 5-percent lidocaine ointment. High-potency topical corticosteroids can be applied at ulceration onset. In cases resistant to topical corticosteroids, oral corticosteroids can help decrease inflammation. Finally, colchicine, dapsone, and thalidomide can be effective for recalcitrant cases (Steward, 2017).

MANIFESTATIONS OF SYSTEMIC DISEASE

Systemic illnesses may initially manifest on the vulvar or vaginal mucosa as bullous, solid, or ulcerative lesions. Examples include systemic lupus erythematosus, human immunodeficiency virus infection, erythema multiforme, Stevens-Johnson syndrome, pemphigus, pemphigoid, sarcoidosis, and syphilis. A thorough history and physical examination usually suffice to link genital lesions with preexisting conditions. However, biopsy of vulvovaginal lesions may provide a new and unexpected diagnosis if the disorder has not yet manifest elsewhere.

Acanthosis Nigricans

This condition is characterized by velvety to warty, brown to black, poorly marginated plaques. These changes are typically found at skin flexures, especially on the neck, axillae, and labiocrural folds (Fig. 18-6, p. 395).

Acanthosis nigricans is commonly associated with obesity, diabetes mellitus, and polycystic ovarian syndrome. Thus, if signs or symptoms of these are present, appropriate evaluation is indicated. Common to these conditions, insulin resistance with compensatory hyperinsulinemia is thought to promote the skin thickening of acanthosis nigricans. Insulin binds to insulin-like growth factor receptors and leads to keratinocyte and dermal fibroblast proliferation (Hermanns-Le, 2004). Rarely, acanthosis nigricans is caused by other insulin-resistance or fibroblast growth-factor disorders (Saraiya, 2013).

Treatment of acanthosis nigricans has not been evaluated in randomized trials. However, weight loss can ameliorate insulin resistance, which may lead to plaque improvement. In those prescribed metformin for glucose control, improved acanthosis nigricans has been demonstrated (Romo, 2008). Topical retinoids may have benefit but are often irritating (Patel, 2018). Last, topical vitamin D analogs such as calcipotriene can promote plaque improvement (Bohm, 1998).

Crohn Disease

Up to one third of women with Crohn disease suffer from anogenital involvement, which may precede gastrointestinal (GI) symptoms and a formal Crohn disease diagnosis. Vulvar lesions are commonly "metastatic" in that they show typical Crohn disease granulomatous inflammation but are not contiguous

FIGURE 4-8 Vulvar Crohn disease. Knife-cut ulcers in the labiocrural folds and perineum are commonly seen with vulvar Crohn disease. (Reproduced with permission from Dr. F. Gary Cunningham.)

with the affected GI site (Sides, 2013). However, vulvar and perianal abscesses and fistulae can extend directly from GI tract lesions. The four manifestation types are vulvar edema (usually asymmetric), ulceration, hypertrophic lesions, and chronic abscesses (Barret, 2014). Linear "knife-cut" ulcerations and other lesions often affect inguinal, labiocrural, and interlabial folds (Fig. 4-8). All can be asymptomatic but may cause burning or pruritus.

Therapy for GI Crohn disease generally benefits external Crohn lesions. Vulvar lesions unrelated to GI disease activity often respond to prolonged courses of oral metronidazole alone or in conjunction with corticosteroids (Andreani, 2010). Anti-TNF-α agents (infliximab or adalimumab) show promising results (Laftah, 2015). Surgery often can be avoided or delayed with appropriate vulvar care, nutrition, and close collaboration with a gastroenterologist. As a last resort, excision of fistulous tracts and other refractory lesions or vulvectomy is an option. However, either can be complicated by poor healing and scarring (Sides, 2013). Regardless of management, recurrence is common.

Behçet Disease

This rare systemic vasculitis most commonly affects patients in their twenties and thirties and those of Asian or Middle Eastern descent. Behçet disease is characterized by mucocutaneous lesions (ocular, oral, and genital) and associated systemic vasculitis. Oral and genital ulcers appear similar to aphthous ulcers and generally heal within 7 to 10 days. Nevertheless, associated pain can be debilitating. Treatment for these lesions mirrors that for aphthous ulcers.

The exact etiology of Behçet disease remains unknown, although genetic and autoimmune etiologies are suspected. Vasculitis dominates the disease process, which may involve the brain, GI tract, joints, lungs, and great vessels. Accordingly, for those suspected of Behçet disease, referral to a rheumatologist for additional testing and treatment is recommended.

DISORDERS OF PIGMENTATION

Benign variations of vulvar, perineal, and perianal skin pigmentation are commonly encountered, especially in women with darker skin. Diffuse areas of increased pigmentation are usually encountered on the labia minora and fourchette. Areas tend to be bilateral and symmetric and have flat tone and normal texture. With gentle stretching, the color attenuates evenly. However, this may also be seen with pigment variation of chronic inflammatory dermatoses.

Some benign vulvar lesions may also be pigmented. These include benign melanosis, lentigines, cherry hemangiomas, angiokeratomas, and seborrheic keratosis (Heller, 2013). Focal dyspigmentation raises concern for premalignant or malignant conditions, and prompt biopsy avoids diagnostic delay. As discussed in Chapter 29 (p. 645), high-grade intraepithelial neoplasia or invasive cancer can appear white (hyperkeratotic) or hyperpigmented and can present with or without symptoms. Melanoma is discussed in Chapter 31 (p. 685).

Nevus

Discrete, rounded, pigmented lesions, known as nevi or moles, are easily overlooked on the vulva. These warrant close surveillance as more than half of all melanomas arise from preexisting nevi (Kaufman, 2005). Congenital and dysplastic nevi have the most malignant potential.

Common nevi are classified into three groups: junctional, compound, and dermal, depending on whether the melanotic nevus cells are located at the epidermis-dermis junction, extend into the dermis, or evolve over time to reside entirely within the dermis. Dermal nevi may appear bluish or have normal skin coloration depending on the depth of the nevus cells and may be raised, papillary, or pedunculated.

Recommendations vary regarding biopsy of pigmented vulvar lesions. The American College of Obstetricians and Gynecologists (2016a) recommends biopsy of all such lesions. Others suggest nevus-sampling criteria used elsewhere on the body. Namely, asymmetry, uneven pigmentation, irregular border, diameter >5 mm, or erosion or fissuring merits biopsy (Edwards, 2010). Burning or itching also raises concern. Histologic atypia requires full lesion excision with adequate margins. Atypia or anatomically challenging biopsies, such as those near the clitoris, may prompt referral to clinicians with specialized knowledge and experience with these lesions. Small, bland nevi that are not biopsied warrant a careful descriptive or photographic entry into the medical record and surveillance at least annually until the lesion is deemed stable. Self-examination is encouraged, and changes in lesion or symptoms are important.

Vitiligo

Loss of epidermal melanocytes can result in depigmented skin, termed vitiligo (Fig. 4-9). No race or ethnicity has greater risks for vitiligo, but the disease may be more disfiguring and distressing for darker-skinned individuals (Grimes, 2005).

Although the etiology remains unknown, genetic factors are most likely (Zhang, 2005). Approximately 20 percent of patients have at least one affected first-degree relative. Vitiligo

FIGURE 4-9 Vulvar vitiligo.

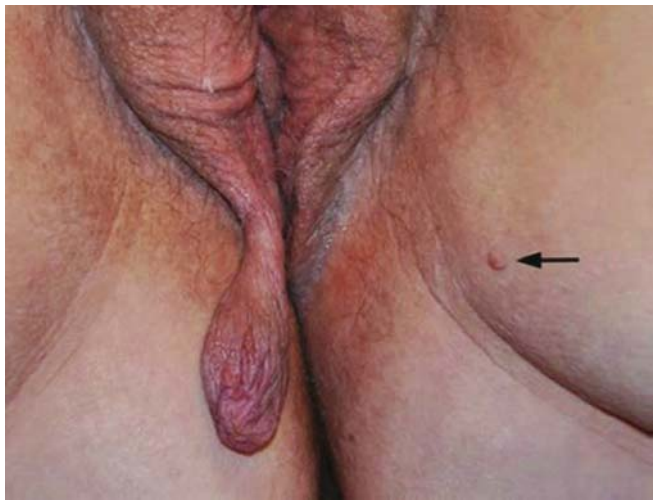

FIGURE 4-10 Vulvar acrochordons (skin tags). Lesions typically are small (*arrow*) and require no intervention. The larger vulvar acrochordon shown here was excised due to mechanical symptoms from its size.

may be mediated by an autoimmune process that destroys melanocytes. Autoimmune diseases such as Hashimoto thyroiditis, Graves disease, diabetes mellitus, rheumatoid arthritis, psoriasis, and vulvar lichen sclerosus are associated with vitiligo (Boissy, 1997; Vrijman, 2012).

Most commonly, depigmentation is symmetric and generalized, although distribution may be acral (limbs, ears) and localized. Sometimes confused with the epithelial changes seen with lichen sclerosus, vitiligo preserves normal skin texture and contour and is otherwise asymptomatic. No cure is presently available for vitiligo, and spontaneous repigmentation is rare. Several treatments for vitiligo include narrowband ultraviolet (UV) B phototherapy, excimer laser therapy, and topical immunomodulators (Baciqalupi, 2012). Most cases are self-limited, and explanation of the condition alone is sufficient.

SOLID VULVAR TUMORS

Most solid vulvar tumors are benign and arise from local tissue. Less commonly, malignant lesions arise on the vulva and are typically of squamous cell epithelial origin. Rarely, solid vulvar tumors develop as metastatic lesions. Accordingly, many growths warrant biopsy if not obviously diagnosed visually.

Epidermal and Dermal Lesions

Acrochordons, commonly known as skin tags, are benign, soft fibroepithelial lesions. Most often seen on the neck, axilla, or groin, these skin-colored polypoid masses are usually devoid of hair and generally measure 1 to 6 mm in diameter but can grow larger (Fig. 4-10). They are mistaken for vulvar condylomata, and therapeutic unresponsiveness by presumed genital warts should prompt removal for histologic analysis. Surgical removal is likewise recommended for chronic irritation or cosmetic concerns. Small lesions are easily removed under local anesthesia in an office setting. Acrochordons have been linked to diabetes mellitus, and insulin-mediated fibroblast proliferation may explain this relationship (Demir, 2002).

Seborrheic keratosis may be observed in women with concurrent lesions on the neck, face, or trunk. These lesions typically appear sharply circumscribed, slightly raised, and waxy or scaly. The malignant potential of these slow-growing lesions is minimal, therefore excision is offered only in cases of discomfort or disfigurement.

Keratoacanthoma is a rapidly growing keratinocyte proliferation originating in a pilosebaceous gland. Rarely developing on the vulva, lesions begin as firm, round papules that progress to a dome-shaped nodule with a central crater. Untreated, the lesion usually spontaneously regresses within 4 to 6 months and leaves only a slightly depressed scar. Controversy surrounds its malignant potential (Ko, 2010; Savage, 2014). Some consider keratoacanthoma benign, whereas others classify it as a well-differentiated squamous cell carcinoma. Nevertheless, its histologic resemblance to this cancer merits surgical excision in most cases with a 4- to 5-mm margin.

Syringoma is a benign eccrine (sweat gland) tumor found most frequently on the lower eyelid, neck, and face. Rarely, the vulva may be involved bilaterally with multiple 1- to 4-mm firm papules. The clinical appearance of vulvar syringoma is not pathognomonic, thus vulvar punch biopsy will establish the diagnosis and exclude malignancy. Treatment is not required. However, for those with pruritus, mild-potency topical corticosteroids and antihistamines may be helpful. In those with refractory pruritus, surgical excision or lesion ablation can be offered.

Subcutaneous Masses

Leiomyoma of the vulva is a rare tumor felt to arise either from smooth muscle within the vulva's erectile tissue or from transmigration through the round ligament. Surgical excision to exclude leiomyosarcoma is sound, and recurrence has been reported (Nielsen, 1996).

Fibroma is a benign tumor rarely arising from deep vulvar connective tissue by fibroblast proliferation. Lesions are primarily found on the labia majora and range from 0.6 to 8 cm in diameter. Larger lesions often become pedunculated with a long stalk and may cause pain or dyspareunia. Surgical excision is indicated for symptomatic lesions or if the diagnosis is unclear.

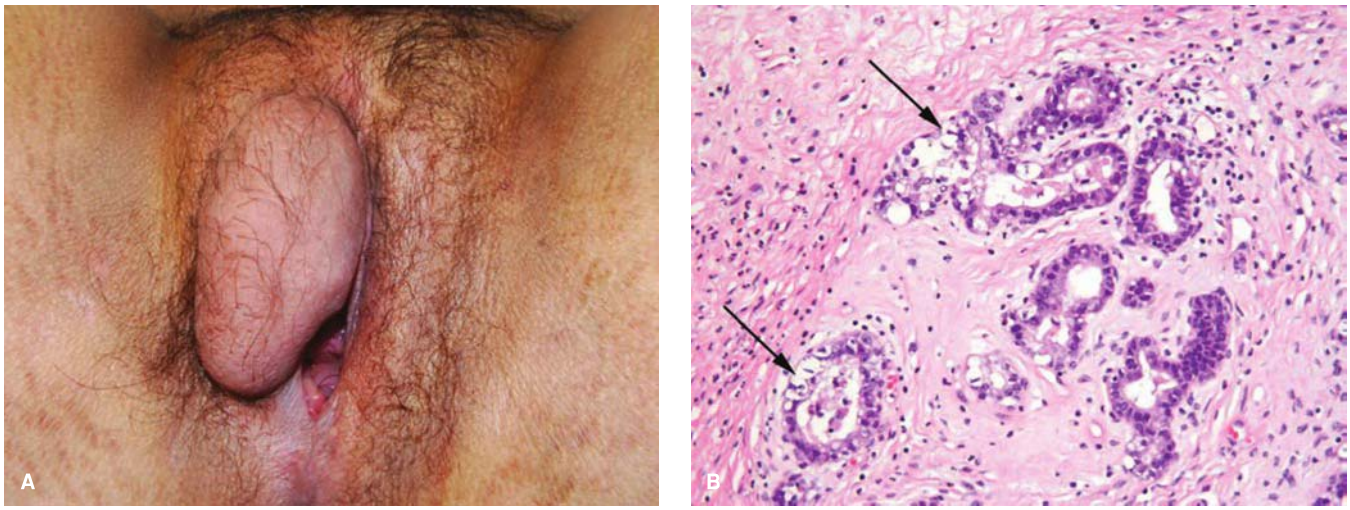

FIGURE 4-11 Ectopic breast tissue. **A.** This chronic vulvar mass grew slightly during pregnancy and then dramatically enlarged 3 days following an uncomplicated vaginal birth. This corresponded with lactation. **B.** Histologic evaluation following excision shows glands typical of breast tissue (*arrow*).

Lipoma is a soft sessile or pedunculated mass composed of mature adipose cells. Similar to fibromas, observation is reasonable in the absence of patient complaints, although symptoms may prompt surgical excision. These lesions lack a fibrous connective tissue capsule. Thus, complete dissection can require a larger incision and can be complicated by bleeding.

Ectopic breast tissue may develop along the theoretical milk lines, which extend bilaterally from the axilla through the breast to the mons pubis. Uncommonly found in the vulva, extramammary breast tissue is hormonally sensitive and may enlarge in response to pregnancy or exogenous hormones (Fig. 4-11). Importantly, these typically soft masses may also develop breast pathologies including fibroadenoma, phyllodes tumor, Paget disease, and invasive adenocarcinoma.

CYSTIC VULVAR TUMORS

Bartholin Gland Duct Cyst and Abscess

Mucus produced to lubricate the vulva originates in part from the Bartholin glands. Obstruction of this gland's duct is common and may follow infection, trauma, mucus changes, or congenitally narrowed ducts. However, the underlying cause is often unclear.

In some cases, cyst contents may become infected and lead to abscess formation. These tend to develop in populations with demographic profiles similar to those at high risk for sexually transmitted infections (Aghajanian, 1994). However, a wide spectrum of organisms has been cultured. *Escherichia coli* is the most common isolate, but other gram-positive and gram-negative aerobes and anaerobes are found (Kessous, 2013; Mattila 1994; Tanaka, 2005). Infrequently, *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is identified.

Diagnosis and Treatment

Most Bartholin gland cysts are small and asymptomatic except for minor discomfort during sexual contact (Fig. 4-12). With larger or infected cysts, however, patients may complain of severe vulvar pain that precludes walking, sitting, or coitus (Fig. 3-18, p. 86).

On physical examination, cysts typically are unilateral, round or ovoid, and fluctuant or tense. If infected, they display surrounding erythema and are tender. The mass is usually located in the inferior labia majora or lower vestibule. Whereas most cysts and abscesses lead to labial asymmetry, smaller cysts may be detected only by palpation. Bartholin abscesses on the verge of spontaneous decompression will exhibit an area of softening, where rupture will most likely occur.

Small, asymptomatic Bartholin gland duct cysts require no intervention except exclusion of neoplasia in women older than 40 years. If symptomatic, a cyst may be managed with one of several techniques. These include incision and drainage (I & D), marsupialization, and Bartholin gland excision, which are described and illustrated in Chapter 43 (p. 980). Abscesses are treated with I & D or marsupialization.

Malignancy

After menopause, Bartholin gland duct cysts and abscesses are uncommon and should raise concern for possible neoplasia.

FIGURE 4-12 Bartholin gland duct cyst seen as an asymmetric bulge in the left lower vestibule.

However, carcinoma of the Bartholin gland is rare, and its incidence approximates 0.1 per 100,000 women (Visco, 1996). Most are squamous carcinomas or adenocarcinomas (Heller, 2014). Given the rarity of these cancers, Bartholin gland excision is typically not indicated. Alternatively, in women older than 40 years, drainage of the cyst and biopsy of cyst wall sites adequately excludes malignancy (Visco, 1996).

Urethral Diverticulum and Skene Gland

Ductal occlusion of the Skene gland or paraurethral glands may lead to paraurethral cystic enlargement and possible abscess formation. Their symptoms and treatment are described in Chapter 26 (p. 581).

Epidermal Inclusion Cysts

These cysts, also known as sebaceous cysts, are commonly found on the vulva, and less so in the vagina. Although histologically similar and lined by squamous epithelium, it is unclear if they represent separate entities. Vulvar epidermoid cysts typically form from plugged pilosebaceous units (Fig. 4-13). However, epidermoid cysts can also follow traumatic implantation of epidermal cells into deeper tissues and are filled with keratin.

Epidermal inclusion cysts are variably sized, are typically round or ovoid, and are skin colored, yellow, or white. Grossly, cysts are usually filled with viscous, gritty, or caseous foul-smelling material. Epidermoid cysts are generally asymptomatic and require no further evaluation. If symptomatic or secondarily infected, incision and drainage is recommended.

FIGURE 4-13 Multiple, mobile, knotty epidermal inclusion cysts line the inner labia majora.

VULVODYNIA

Shown in Table 4-6, the ISSVD in 2015 defined *vulvodynia* as "vulvar pain of at least 3 months duration, without clear identifiable cause, which may have potential associated factors" (Bornstein, 2016). In distinction, *persistent vulvar pain* is attributable to a specific condition (see Table 4-6). The term *vestibulitis* was eliminated from ISSVD terminology because inflammatory changes are not consistently documented.

From limited studies, the prevalence of vulvodynia in the general population is 3 to 11 percent (Lavy, 2007; Reed, 2004, 2014). One study estimated that each year 1 in 50 women will develop vulvodynia (Reed, 2008). All ethnicities and a wide age range are affected.

The underlying cause of vulvodynia is multifactorial and varies among individuals (Stockdale, 2014). Potential factors associated with vulvodynia include other pain syndromes, genetic influences, hormonal factors, inflammation, musculoskeletal dysfunction, neurologic mechanisms, psychosocial elements, and structural defects (Bornstein, 2016). Ultimately, identification of these associated factors will guide individualized treatment planning.

TABLE 4-6. 2015 Consensus Terminology and Classification of Persistent Vulvar Pain and Vulvodynia

Vulvar pain caused by a specific disorder
Infectious (e.g., recurrent candidiasis, herpes)
Inflammatory (e.g., lichen sclerosus, lichen planus, immunobullous disorders)
Neoplastic (e.g., Paget disease, squamous cell carcinoma)
Neurologic (e.g., postherpetic neuralgia, nerve compression or injury, neuroma)
Trauma (e.g., female genital cutting, obstetrical)
Iatrogenic (e.g., postoperative, chemotherapy, radiation)
Hormonal deficiencies (e.g., genitourinary syndrome of menopause [vulvovaginal atrophy], lactational amenorrhea)
Vulvodynia—vulvar pain of at least 3 months' duration, without clear identifiable cause, which may have potential associated factors
The following are the descriptors:
Localized (e.g., vestibulodynia, clitorodynia) or generalized or mixed (localized and generalized)
Provoked (e.g., insertional, contact) or spontaneous or mixed (provoked and spontaneous)
Onset (primary or secondary)
Temporal pattern (intermittent, persistent, constant, immediate, delayed)

From Bornstein, 2016, with permission.

TABLE 4-7. Appropriate Vulvodynia Questions

Pain onset date? A precipitating event?
Pain onset gradual or sudden?
Is pain intermittent, constant, immediate, or delayed?
Describe the pain and its intensity.
Aggravating factors? Is pain provoked or spontaneous?
Relieving factors? Prior therapy?
Associated symptoms? Urinary? GI? Dermatologic?
Does pain lessen quality of life? Limit activities? Disturb sexual function?

GI = gastrointestinal

Diagnosis

Typically, evaluation and management are delayed for years due to patient embarrassment, attempts at self-treatment, and lack of knowledge that it is a medical condition. Diagnosis and treatment delays, often by multiple providers, are common (Harlow, 2003, 2014).

An evidence-based approach to diagnose vulvodynia and its associated factors is essential (Haefner, 2005; Stockdale, 2014). Given that vulvodynia is a diagnosis of exclusion, a thorough history that includes medical, sexual, and surgical inquiries aids diagnosis (Table 4-7) (American College of Obstetricians and Gynecologists, 2016b).

As noted, vulvodynia is categorized as spontaneous (unprovoked), triggered by physical pressure (provoked), or mixed. Pain is further categorized by its general or local anatomic distribution, its onset, and its temporal pattern. Sensations may be constant, intermittent, or episodic with exacerbations noted premenstrually (Arnold, 2006). Vulvodynia is described variably as burning, rawness, itching, or cutting pain within affected areas (Bergeron, 2001).

Questioning seeks to identify frequently associated pain syndromes or psychologic disorders. These may include irritable bowel syndrome, interstitial cystitis, painful bladder syndrome, fibromyalgia, and mood or posttraumatic stress disorders. A history of recurrent infectious diseases such as herpes simplex or zoster is sought. Past surgical or obstetric procedures may help identify pudendal nerve injury. A sexual history may reveal clues of past or current abuse, unfavorable coital patterns, female sexual dysfunction, relationship disharmony, and contraceptive modalities that could provoke vulvodynia (Chap. 14, p. 313). Additionally, clinicians inquire about recurrent candidiasis; prior genital trauma, including childbirth-related injuries; and current hygiene practices. Specifically, questions regarding genital shaving, type of undergarment fabric worn, and use of products in Table 4-1 can be helpful. Prior therapies are documented to avoid unnecessary treatment repetition.

Next, a thorough examination excludes other possible pathologies. Inspection of the external vulva for lesions or irritation is followed by examination of the vestibule looking for focal, usually mild, erythema at vestibular gland openings. Use of a magnifying lens is important, and directed biopsies of nonerythematous epithelial changes may be helpful. Of note, Bowen and associates (2008) found clinically relevant dermatoses in 61 percent of refractory vulvodynia patients referred to their tertiary care vulvovaginal clinic.

Systematic pain mapping of the vestibule, perineum, and inner thigh is completed, and documentation serves as a reference to assess treatment success (see Fig. 4-1). A cotton swab is used to check for allodynia and hyperesthesia. The swab end can first be unwound to form a cotton-fiber wisp. Subsequently, the wooden stick is broken to form a sharp point to retest the same areas. Pain scale scores of mild, moderate, or severe are recorded and followed over time.

Last, a saline "wet prep" of vaginal secretions and vaginal pH testing assist in excluding hormonal or infectious causes. Testing as clinically indicated for yeast and HSV is similarly helpful (Chap. 3, pp. 58 and 64).

Treatment

Like other chronic pain conditions, vulvodynia is challenging to treat. Importantly, all vulvodynia treatment is individualized and may require a multidisciplinary approach that includes medical therapy, pelvic floor physical therapy, and psychotherapy. However, due to the lack of well-designed randomized trials, no specific therapy for vulvodynia demonstrates superiority. Often, a combination of several therapeutic options is required to relieve symptoms (Haefner, 2005; Landry, 2008). Approaches are described further by Stockdale (2014) and the American College of Obstetricians and Gynecologists (2016b). Encouragingly, from one 2-year study, the annual remission rate for women with vulvodynia was 11 percent (Reed, 2008). Without improvement, surgical excision is a final option.

Behavioral and Physical Therapy

The first step in managing all vulvar disorders includes vulvar care as summarized in Table 4-2. Also, provision of accurate medical information can help resolve some patient concerns and questions associated with vulvodynia. The National Vulvodynia Association offers patient information and support and can be accessed online at www.nva.org.

Compared with the general population, no differences in marital contentment or psychologic distress are found (Bornstein, 1999). That said, education regarding foreplay, sexual positions, lubrication, and alternatives to vaginal intercourse are offered if potentially helpful. Female sexual dysfunction and its treatment are further discussed in Chapter 14 (p. 312).

Back pain, pelvic floor muscle spasm, or vaginismus may be the underlying cause of vulvodynia, and pelvic floor muscle examination is described and illustrated in Chapter 12 (p. 260). A physical therapist familiar with treating these concerns may provide internal and external massage, myofascial release techniques, acupressure, joint manipulation, electrical stimulation, therapeutic ultrasonography, and pelvic floor muscle retraining to improve symptoms (Bergeron, 2002).

Dietary oxalates excreted into urine have been suggested to aggravate symptoms, but evidence is limited and shows contradictory results (Baggish, 1997; Harlow, 2008). Similarly, support for supplementing with calcium citrate to balance the urine oxalates is scarce (Solomons, 1991).

TABLE 4-8. Nonsurgical Vulvodynia Treatment

Vulvar care	See Table 4-2
Topical agents	2% lidocaine jelly or 5% lidocaine ointment, apply precoitally Gabapentin 2% to 6% ointment or cream, apply two or three times daily
Antidepressant	Amitriptyline, initially 5–25 mg orally daily, then increase daily dose by 10–25 mg each week. Maximum dose 150 mg daily Duloxetine (Cymbalta), 30 mg orally daily. May increase to 60 mg daily
Anticonvulsant	Gabapentin, 100 mg orally three times daily and gradually increase as needed over 6–8 weeks. Maximum dose 1200 mg three times daily.
Local injection	1 mL 1% lidocaine plus 1 mL betamethasone (6 mg/mL) or 10 mg lidocaine plus 40 mg methylprednisolone acetate in 10 mL normal saline
Biofeedback	
Sex counseling	

Data from Boardman, 2008; Murina, 2001; Reed, 2006; Segal, 2003; Stockdale, 2014.

Medications

Agents for vulvodynia treatment may be administered topically, orally, or intralesionally (Table 4-8). Of topical agents, 2-percent lidocaine mucosal jelly or 5-percent lidocaine ointment applied sparingly to the vestibule prior to coitus is often a first-line choice. However, randomized trials do not show a statistically significant difference between these and placebo. Other topical anesthetic preparations are reported to have variable success. However, caution is exercised with benzocaine, which is associated with higher rates of contact dermatitis.

Eva and coworkers (2003) found lower estrogen-receptor expression in women with vulvodynia. However, topical or intravaginal estrogen therapy has yielded mixed results.

As reported by Boardman and associates (2008), topical gabapentin cream is well tolerated, is effective, and avoids the potential side effects of systemic gabapentin therapy. In their study, 0.5 mL of a compounded 2-, 4-, or 6-percent gabapentin-containing cream was applied three times daily for at least 8 weeks to affected vulvar areas.

Of oral medications, antidepressants and anticonvulsants are reported to help vulvodynia. However, polypharmacy is ideally avoided, and clinicians prescribe one drug at a time. Additionally, contraception is required for reproductive-aged patients. Tricyclic antidepressants (TCAs) are widely used for vulvodynia, and reported response rates may reach nearly 60 percent in nonrandomized trials (Pagano, 1999; Reed, 2006). In our experience, amitriptyline started at doses of 5 to 25 mg orally nightly and increased as needed by 10 to 25 mg each week yields good results for some patients. Final daily doses do not exceed 150 mg. Importantly, compliance is encouraged during the nearly 4-week lag required to achieve significant pain relief. Alternatively, duloxetine (Cymbalta), which is a serotonin-norepinephrine-reuptake inhibitor, has fewer anticholinergic effects.

Cases resistant to antidepressants may be treated with the anticonvulsant gabapentin (Harris, 2007). Oral gabapentin is initiated at a dosage of 100 mg three times daily and gradually increased within 6 to 8 weeks to a maximal daily dose of 1200 mg three times daily. Once this dose is reached, pain is reassessed after 1 to 2 weeks (Haefner, 2005). Most support for gabapentin comes from case series. One recent randomized trial found no improvement in pain scores but did find improvement in sexual functioning scores (Brown, 2018; Bachmann, 2019).

Topical corticosteroids generally do not help patients with vulvodynia. However, injections using a combination of corticosteroids and local anesthetics have been used for localized vulvodynia in case reports (Murina, 2001; Segal, 2003). Alternatively, botulinum toxin A injection into the levator ani muscles has been reported effective for vulvodynia-related vaginismus (Bertolasi, 2009; Morrissey, 2015).

Surgery

Women with vulvodynia who fail to improve despite aggressive medical therapy are candidates for surgery. Options include local excision of a precise pain locus, complete resection of the vestibule (vestibulectomy), or resection of the vestibule and perineum (perineoplasty) (Chap. 43, p. 988). From a series of 155 treated women, Traas and colleagues (2006) reported high success rates with vestibulectomy among women younger than 30 years. Perineoplasty is the most extensive of the three procedures. Its incision extends from just below the urethra to the perineal body, usually terminating above the anal orifice. This procedure may be selected if significant perineal scarring is suspected to contribute to dyspareunia. Overall, improvement rates for appropriately selected patients are high following vulvar excision procedures. However, surgery is reserved for those with severe, localized, long-standing vestibular pain who have failed significant attempts at conservative, multidisciplinary management. It is best performed by gynecologists skilled in vulvar excisional surgery.

VULVOVAGINAL TRAUMA

Vulvar Hematoma

This may develop in the relatively vascular vulva following straddle injury, trauma from coitus or assault, or vulvovaginal

FIGURE 4-14 Vulvar hematoma.

procedures. Hematomas may develop within subcutaneous tissues or within the superficial perineal pouch of the anterior perineal triangle (Fig. 38-26, p. 815). Within the latter, laceration of the vestibular bulb, clitoral crus, or branches of the internal pudendal vessels may create a sizable mass (Fig. 4-14). Given the protected anatomic location and adipose padding of the labia majora, traumatic vulvar injuries are rare in adults. These are much more frequent in children who lack such padding. Differentiating straddle injury and sexual abuse in children is often challenging, as injury patterns are not reliably discriminating.

Often requiring a general anesthetic, thorough examination of the vulva and vagina will estimate hematoma stability and the integrity of the surrounding bowel, bladder, urethra, and rectum. If no associated organ injury is found, the venous origin of most vulvar hematomas makes them candidates for conservative management with cool packs, pain control, and Foley catheter bladder drainage as needed. In general, large or rapidly expanding hematomas are surgically explored to secure bleeding vessels. However, following incision and clot evacuation, a cavity is often seen without an identifiable bleeding vessel. To prevent reaccumulation, the cavity is closed in layers with absorbable or delayed-absorbable suture using a running or interrupted stitch closure.

Vaginal Laceration

Penetrating trauma accounts for most vaginal injuries. Common causes include pelvic fracture, forced inanimate objects, coitus, and hydraulic forces such as those experienced with water skiing. Atrophic vaginal changes can predispose to injury.

With extensive laceration, examination under anesthesia is usually necessary to perform a thorough assessment and to exclude intraperitoneal damage. Moreover, if the peritoneal cavity has been breached, abdominal cavity exploration by laparotomy or laparoscopy is often needed to exclude visceral injury and supralevator or retroperitoneal hematoma.

Treatment goals include hemostasis and restoration of normal anatomy. Irrigation, debridement, and primary repair are key steps during initial management. The vaginal mucosa is typically reapproximated with running or interrupted stitches with absorbable or delayed-absorbable suture. Uncommonly, infection dictates laceration healing by secondary intention. Nonexpanding hematomas may be managed conservatively, whereas expanding masses often require evacuation and isolation of bleeding vessels. Angiography coupled with embolization is another option. With laceration or hematoma, postoperatively, a vaginal pack can help tamponade any continued bleeding.

VAGINAL CONDITIONS

Foreign Body

Trauma or chronic irritation from a foreign body placed into the vagina can affect all ages. Objects vary by age group, and small objects may become lodged in a child's vagina during play (Fig. 15-11, p. 329). An adolescent may be unable to retrieve or may be unaware of a vaginal tampon or piece of broken condom. In adults, sexual misadventure or abuse can usually explain most objects found.

Three notable items include a retained tampon or contraceptive sponge and the vaginal pessary. Women with a retained tampon or sponge typically complain of foul-smelling vaginal discharge with some associated pruritus, discomfort, or unscheduled bleeding. A history of multiple unsuccessful retrieval attempts may be elicited. In the absence of leukocytosis, fever, or evidence of an endometritis or salpingitis, simple removal is sufficient treatment. Vaginal lavage to cleanse the vagina is not indicated and may actually increase the risk of ascending infection. Toxic shock syndrome has been described with both tampons and contraceptive sponges, and its management is outlined in Chapter 3 (p. 83). Vaginal pessaries are frequently selected to conservatively treat pelvic organ prolapse or incontinence. Associated complications with these devices and their management are described fully in Chapter 24 (p. 548).

Desquamative Inflammatory Vaginitis

Desquamative inflammatory vaginitis (DIV) is likely a severe form of aerobic vaginitis (AV) (Sherrard, 2018). This uncommon chronic inflammatory vaginitis develops primarily in perimenopausal women, and white women appear to be more often affected. Although the etiology of DIV is unknown, it may represent a variant of erosive vaginal lichen planus (Edwards, 1988). In contrast, AV may be secondary to an overgrowth of aerobic microbes such as *E coli*, group B streptococcus, and *Staphylococcus aureus* (Donders, 2002). Possible triggers include diarrhea or antibiotic use (Bradford, 2010).

Copious vaginal discharge, introital burning, dyspareunia, and vaginal irritation, all refractory to common therapies, is a typical presentation. On examination, a diffuse, exudative, purulent yellow or green discharge is seen on the vaginal walls. Varying degrees of vestibular-vaginal erythema or ulceration are noted. Microscopy reveals many polymorphonuclear and parabasal cells but a reduced lactobacilli population. Pathogens such as trichomonads or yeast forms are absent. The vaginal

pH is elevated, and exclusionary test results for gonorrhea and Chlamydia infection are negative. The profuse leukorrhea may lead to an erroneous diagnosis of pelvic inflammatory disease or cervicitis, but pelvic tenderness is absent.

Although no randomized clinical trials are available, Sobel (2011) reports favorable outcomes with 2-percent intravaginal clindamycin cream or an intravaginal hydrocortisone cream or suppositories for 4 to 6 weeks. Whether the efficacy of clindamycin is due to its antibacterial or antiinflammatory properties is unknown (Bradford, 2010). This is a chronic condition, and prolonged treatment courses, relapses, and need for retreatment are common.

Diethylstilbestrol-induced Reproductive Tract Abnormalities

In the mid-1900s, diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed to women in the United States for several pregnancy-related problems. Daughters exposed in utero to DES had congenital reproductive tract anomalies and demonstrated higher rates of vaginal clear cell adenocarcinoma (Herbst, 1971). More commonly, *vaginal adenosis,* which is an area(s) of columnar epithelium within the vaginal squamous mucosa, is found in these women. Vaginal adenosis typically appears as red, granular patches. Symptoms include vaginal irritation, vaginal discharge, and intermenstrual or postcoital bleeding. A fuller discussion of DES-related defects is found in Chapter 19 (p. 424).

Gartner Duct Cyst

Most vaginal cysts are epidermoid cysts, urethral diverticula, or Gartner duct cysts. The last are uncommon vaginal cysts developing from mesonephric (Wolffian) duct remnants (Chap. 19, p. 406). They are typically asymptomatic and found within the lateral vaginal wall during routine examination. Symptoms, if present, include dyspareunia, vaginal pain, and difficulty inserting tampons. Examination reveals a tense cyst that is palpable or seen to bulge beneath the vaginal wall. Observation is reasonable in most cases. Marsupialization or excision may be appropriate for symptomatic Gartner duct cysts.

CERVICAL LESIONS

Eversion

The squamocolumnar junction (SCJ) borders between the columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. As described in Chapter 29 (p. 621), endocervical tissue in some women may migrate outward from the endocervical canal in a process termed *eversion*, which is thought to be hormonally mediated. As a result, the SCJ lies further distally from the external cervical os. Eversion is a normal finding. However, asymmetry of the columnar epithelium surrounding the cervical os can mimic an erosive lesion, and cervical biopsy can aid clarity in this case.

Nabothian Cyst

Mucus-secreting columnar cells line the endocervical canal. During squamous metaplasia, squamous epithelium may cover functional glandular cells, and secretions may accumulate. As this benign process continues, smooth, clear, pale white or yellow, rounded elevations can form and are visible during routine examination (Fig. 4-15). They are also frequently seen as well-defined anechoic sonolucency along the endocervical canal (Fig. 2-14, p. 37).

FIGURE 4-15 Cervical nabothian cyst (*arrow*) is seen as a raised, symmetric, smooth, yellow lesion on the ectocervix.

Nabothian cysts typically do not warrant therapy. However, if they grow large enough to make Pap testing or cervical examination difficult or cause symptoms, they can be opened with a biopsy forceps and drained. Moreover, if the diagnosis of a cervical mass is uncertain, biopsy for histologic confirmation is obtained.

Endocervical Polyp

One of the most common benign neoplasms of the cervix is a hyperplastic projection of endocervical tissue known as an *endocervical polyp* (Fig. 8-10, p. 190). These are usually found during routine pelvic examination and are generally asymptomatic. Polyps may be associated with leukorrhea or postcoital spotting, and additional discussion is found in Chapter 8.

Cervical Stenosis

This narrowing of the cervical canal or opening may be congenital or acquired. Congenital stenosis is rare and likely due to segmental müllerian hypoplasia (Chap. 19, p. 421). In contrast, acquired stenosis is usually iatrogenic due to scarring after cervical excisional procedures such as cold-knife conization and loop electrosurgical excision. This complication is estimated to follow 3 to 8 percent of such procedures (Brun, 2002). Infection, neoplasia, severe atrophy, and radiation changes are less frequent causes.

Diagnosis is based on symptoms and physical findings, as a precise and universally accepted definition is lacking. Symptoms of stenosis in menstruating women include dysmenorrhea, amenorrhea, and infertility. An inability to introduce a dilator into the endocervical canal is generally considered diagnostic. Postmenopausal women are usually asymptomatic until fluid, exudates, or blood accumulates behind the obstruction. These collections are discussed additionally in Chapter 9 (p. 212). If

obstruction is complete, a soft, enlarged uterus from trapped intracavitary fluid is sometimes palpable.

Cervical stenosis is relieved by introduction of dilators, which may require anesthesia and treatment may be followed by recurrences. Preprocedural misoprostol may aid by softening the cervix (Chap. 41, p. 899). In postmenopausal women, pretreatment for several weeks with vaginal estrogen cream may also assist dilation. Surgical techniques to overcome stenosis are described fully in Chapter 41 (p. 903).

CHAPTER 5

Contraception and Sterilization

MEDICAL ELIGIBILITY CRITERIA 111
TOP-TIER CONTRACEPTIVE METHODS 113
SECOND-TIER CONTRACEPTIVE METHODS 121
THIRD-TIER CONTRACEPTIVE METHODS 128
FOURTH-TIER CONTRACEPTIVE METHODS 130
EMERGENCY CONTRACEPTION 131
REFERENCES 132

Today, the variety of effective fertility regulation methods continues to grow. Contraceptive availability is paramount for the care of women, as approximately half of pregnancies in the United States are unintended (Finer, 2016). And related, in 2014, nearly 11 percent of sexually active fertile women in the United States not pursuing pregnancy did not use any birth control method (Kavanaugh, 2018). These statistics have prompted a reexamination of contraceptive counseling to prevent unplanned pregnancy.

Contraceptive methods are grouped according to their effectiveness. *Top-tier* or *first-tier methods* are those that are most effective and are characterized by their ease of use (Fig. 5-1). These methods require minimal user motivation or intervention and have a typical-use pregnancy rate <1 per 100 women during the first year of use (Table 5-1) (Guttmacher Institute, 2018; Trussell, 2018). As expected, these first-tier methods provide the longest duration of contraception after initiation and require the fewest number of return visits. Top-tier methods include various methods of male and female sterilization, intrauterine contraceptive devices, and contraceptive implants. The last two are considered *long-acting reversible contraceptives (LARCs)*. Although counseling is provided for all contraceptive methods, a reduction in the unintended pregnancy rate may be better achieved by increasing top-tier method use.

Second-tier methods include systemic hormonal contraceptives that are available as oral tablets, intramuscular injections, transdermal patches, or transvaginal rings. In sum, their typical-use pregnancy rate is 4 to 7 per 100 users during the first year (see Table 5-1). Perfect-use rates reflect the pregnancy rate if a method is used flawlessly. With second-tier methods, the greater difference between perfect- and typical-use rates most likely stems from a failure to redose at the appropriate interval. Automated reminder systems for these second-tier methods have shown limited efficacy (Halpern, 2013).

Third-tier methods include condoms for men and women, withdrawal, and fertility awareness methods such as cycle beads. The typical-use pregnancy rate is 13 to 24 pregnancies per 100 users in the first year (Guttmacher Institute, 2018). However, efficacy rises with consistent and correct use.

Fourth-tier methods include spermicidal preparations, which have a typical-use failure rate of 28 percent per 100 first-year users (Guttmacher Institute, 2018).

MEDICAL ELIGIBILITY CRITERIA

In 2016, the Centers for Disease Control and Prevention published updated *United States Medical Eligibility Criteria (US MEC)* for contraceptive use in the United States (Curtis, 2016).

TABLE 5-1. Contraceptive Failure Rates During the First Year of Method Use in Women in the United States

Method[a]	Perfect Use	Typical Use
Top tier: most effective		
Intrauterine devices:		
52-mg LNG-IUS	0.1	0.1
T 380A copper	0.6	0.8
Etonogestrel implant	0.1	0.1
Female sterilization	0.5	0.5
Male sterilization	0.1	0.15
Second tier: very effective		
Combination pill	0.3	7
Vaginal ring	0.3	7
Patch	0.3	7
DMPA	0.2	4
Progestin-only pill	0.3	7
Third tier: effective		
Condom		
Male	2	13
Female	5	21
Diaphragm with spermicides	16	24
Fourth tier: least effective		
Spermicides	18	28
Sponge		
Multiparas	20	27
Nulliparas	9	14

[a]Methods organized according to tiers of efficacy.
DMPA = depot medroxyprogesterone acetate;
LNG-IUS = levonorgestrel-releasing intrauterine system.

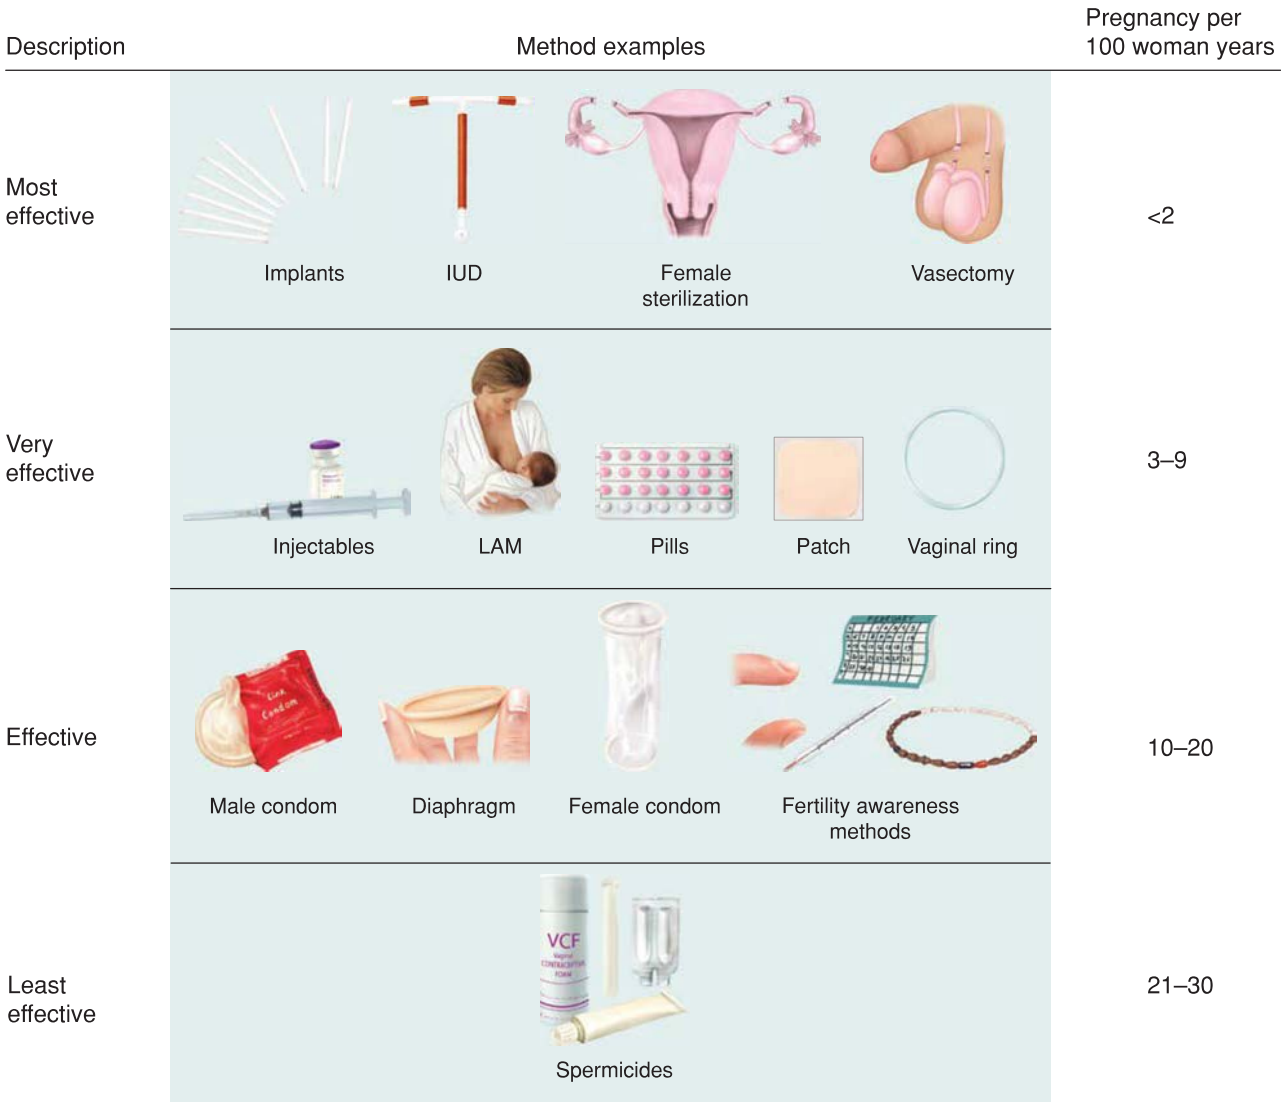

FIGURE 5-1 Contraceptive methods arranged by effectiveness.

These US MEC guidelines are available and updated regularly at the CDC website: www.cdc.gov/reproductivehealth/contraception/mmwr/mec/summary.html. In the US MEC, many contraceptive methods are classified into six groups by their similarity: combination hormonal contraceptive (CHC), progestin-only pill (POP), depot medroxyprogesterone acetate (DMPA), implants, levonorgestrel-releasing intrauterine system (LNG-IUS), and copper intrauterine device (Cu-IUD). For a given health condition, each method is categorized 1 through 4. The score describes a method's safety profile for a typical woman with that condition: (1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, or (4) method poses unacceptably high health risk.

Lactation

Lactation is one factor addressed in the US MEC guidelines. Approximately 20 percent of breast-feeding women will ovulate by 3 months postpartum. Ovulation often precedes menstruation, and these women are at risk for unplanned pregnancy. For women who breastfeed intermittently, effective contraception should begin as if they were not breastfeeding. Moreover, contraception is essential after the first menses unless pregnancy is planned.

Of available methods, the Cu-IUD does not affect lactation because it lacks hormones. The category 2 status in Table 5-2 reflects a higher rate of expulsion if placed place in the puerperium but later than 10 minutes after delivery.

Starting hormonal contraceptives during the puerperium is ideally a shared decision-making process between provider and new mother (Bryant, 2019). Theoretically, systemic progestins may interfere with initial breast milk production. This is reflected in their peripartum US MEC category 2 status during the first 4 weeks postpartum. In reviews, authors describe the lack of evidence to support a negative effect of progestin contraception on lactation (Gurtcheff, 2011; Lopez, 2015c; Phillips, 2016; Tepper, 2016b). However, because progestins are metabolized variably among individuals, alteration in breastfeeding due to individual differences is possible. CHCs are category 2 status or higher because the estradiol component may raise the risk of venous thromboembolism (VTE), especially during the puerperium.

TABLE 5-2. U.S. Medical Eligibility Criteria for Use of Various Contraceptive Methods While Breastfeeding

Method[a]	Category
CHCs[b]	
Breastfeeding	
<21 d	4
21 d–<30 d	3
30–42 d[c]	2
>42 d	2
Non-breastfeeding	
<21 d	4
21–42 d[c]	2
>42 days	1
DMPA, POPs, Implants	
Breastfeeding	
<1 month	2
≥1 month	1
Non-breastfeeding	1
LNG-IUS	
Breastfeeding or not	
<10 min	2
10 min to ≤4 weeks	2
≥4 weeks	1
Puerperal sepsis	4
Cu-IUD	
Breastfeeding or not	
<10 min	1
10 min to ≤4 weeks	2
≥4 weeks	1
Puerperal sepsis	4

[a]Time reflects time from delivery.
[b]Combined hormonal contraceptive (CHC) group includes pills, vaginal ring, and patch.
[c]Associated risks that increase puerperal category score include: age ≥35, transfusion at delivery, BMI ≥30, PPH, cesarean delivery, smoking, preeclampsia.
Cu-IUD = copper-bearing intrauterine device; DMPA = depot medroxyprogesterone acetate; LNG-IUS = levonorgestrel-releasing intrauterine system; POPs = progestin-only pills.
Summarized from Curtis, 2016.

Adolescents

The adolescent birth rate in the United States reached an all-time low in 2017 (Martin, 2018). Despite this, adolescent pregnancy rate in this country is the highest among industrialized countries and is 22 births per 1000 women aged 15 to 19 years. IUDs and implants are safe for adolescents and thus are recommended by national bodies such as the American College of Obstetricians and Gynecologists (2018a) and the American Academy of Pediatrics (2014). Importantly, in 2011, 75 percent of adolescent pregnancies were unintended (Finer, 2016). Thus, effective contraception counseling ideally is provided *before* the onset of sexual activity. In most states, minors have explicit legal authority to consent to contraceptive services, and in many areas, publicly funded clinics provide free contraception to adolescents (Guttmacher Institute, 2014). Moreover, contraception can be provided without a pelvic examination or cervical cancer screening.

Perimenopause

In the perimenopause, ovulation becomes irregular and fertility wanes. However, pregnancies do occur, and in women aged >40 years, nearly half of all pregnancies are unintended (Finer, 2011). Importantly, pregnancy with advanced maternal age carries greater risk for pregnancy-related morbidity and mortality. Women in this group may also have coexistent medical problems that may preclude certain contraceptive methods. Last, perimenopausal symptoms may be improved with hormonal contraceptive methods. Women are encouraged to continue contraceptive use until they have achieved a full year of amenorrhea.

TOP-TIER CONTRACEPTIVE METHODS

Intrauterine Contraception

Intrauterine contraception (IUC) is now used by almost 12 percent of all contraceptive users in the United States (Fig. 5-2) (Guttmacher Institute, 2018). This is a sixfold rise since 2002. Still, this rate is much lower compared with the worldwide IUC use rate of 14 percent and the rate in China (40 percent) (United Nations, 2013).

Some barriers to IUC use in the United States include cost, politics, and provider failure to offer or encourage this method. Despite higher up-front costs, the extended span of effective IUC use results in competitive cost effectiveness compared with other contraceptive forms.

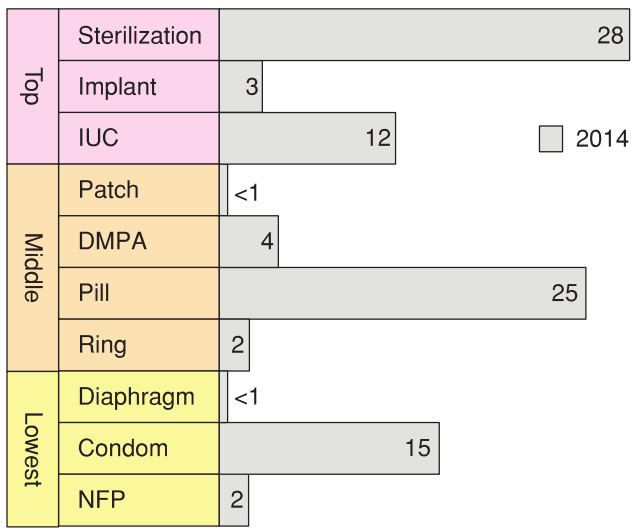

FIGURE 5-2 Rates of contraceptive methods used in the last month by women in the United States, 2014. These do not sum to 100 percent, as withdrawal method and emergency contraception values were not included. DMPA = depot medroxyprogesterone acetate. IUC = intrauterine contraception; NFP = natural family planning.

TABLE 5-3. Properties of Intrauterine Devices

Active Agent	Quantity of Active Agent	Width × Height (mm)	Inserter Tube Diameter (mm)	FDA-Approved Duration of Use (years)	String Color	Silver Ring	Brand Name
LNG	52 mg	32 × 32	4.4	5	Tan	No	Mirena
LNG	52 mg	32 × 32	4.8	5	Blue	No	Liletta
LNG	19.5 mg	28 × 30	3.8	5	Blue	Yes	Kyleena
LNG	13.5 mg	28 × 30	3.8	3	Tan	Yes	Skyla, Jaydess
Copper	380 mm^2	32 × 36	—	10	White	No	ParaGard

LNG = levonorgestrel.

Levonorgestrel-Releasing Intrauterine System

These contraceptives have become more popular in the United States, and currently four types of levonorgestrel-releasing intrauterine systems are approved by the Food and Drug Administration (FDA) (Table 5-3). These contraceptive systems are T-shaped polyethylene structures with the stem encased by a cylinder containing polydimethylsiloxane and levonorgestrel (Fig. 5-3). The cylinder has a permeable membrane that regulates continuous daily hormone release. Although similarly shaped, each device type can be distinguished by its size, string color, and presence or absence of a silver band at the junction of the stem and arms.

Several progestin-mediated mechanisms may explain the contraceptive action of the LNG-IUS. The progestin renders the endometrium atrophic; it stimulates thick cervical mucus that blocks sperm penetration into the uterus; and it may decrease tubal motility, thereby preventing ovum and sperm union. The progestin may also inhibit ovulation, but this is inconsistent (Nilsson, 1984).

Shown in Table 5-4 are the contraindications to use of LNG-IUS. Women who have had a prior ectopic pregnancy may be at higher risk for another because of diminished tubal motility from progestin action. In women with uterine leiomyomas, placement of the LNG-IUS may be problematic if the uterine cavity is distorted. Although not a strict limit, many studies have included only uteri measuring ≤12-week size.

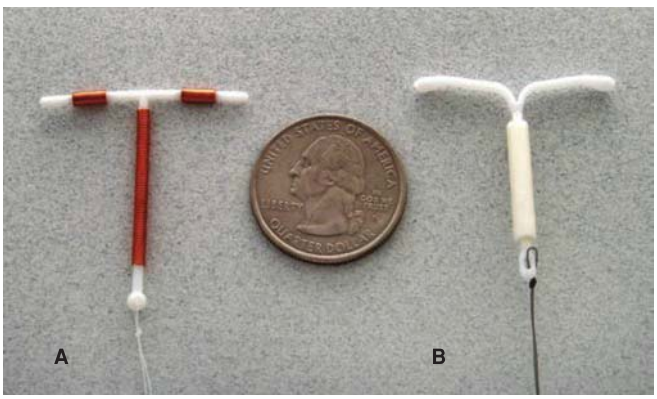

FIGURE 5-3 Intrauterine contraceptive devices. **A.** Copper-containing device. **B.** Levonorgestrel-releasing device.

Copper-T 380A Intrauterine Device

Marketed as ParaGard, this device is composed of a stem wrapped with 314 mm^2 of fine copper wire, and each arm has a 33-mm^2 copper bracelet. The sum of these is 380 mm^2 of copper. As shown in Figure 5-3, two strings extend from the base of the stem. The Cu-T 380A is approved for 10 years of continuous use, although it has been shown to prevent pregnancy with continuous use for up to 20 years (Bahamondes, 2005).

The intense local inflammatory response induced in the uterus by copper-containing devices leads to lysosomal activation and other inflammatory actions that are spermicidal (Alvarez, 1988; Ortiz, 1987). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. And finally, the endometrium becomes hostile for implantation.

Counseling for Intrauterine Contraception

Infection. Several improvements have created safer and more effective models. That said, some unwanted side effects and misconceptions persist surrounding their use.

First, fear of IUD-associated infections precluded use in the past. Improved device design has mitigated these concerns appreciably. In addition, several well-designed studies have shown that sexual behavior and sexually transmitted disease (STD) are important risk factors.

With current devices, prophylactic antibiotics are unnecessary with insertion for women at low risk for STDs (American College of Obstetricians and Gynecologists, 2018c). Of the <1 in 100 women who develop an infection within 20 days of IUD insertion, most have a concomitant unrecognized cervical infection. Accordingly, women at higher risk for lower genital tract STDs are screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2015; Turok, 2016). If this STD test result is positive and the patient is asymptomatic, the IUD may remain and targeted antibiotics are provided. Alternatively, a small number of pelvic infections are presumed to be caused by intrauterine contamination with normal flora at the time of insertion. Thus, antibiotics selected for treatment of symptomatic pelvic infection within the early weeks following IUD insertion should be broad-spectrum to adequately cover all these organisms.

Long-term IUC use is not associated with a greater pelvic infection rate in women at low risk for STDs. Indeed, these long-term users have a pelvic infection rate comparable with

TABLE 5-4. Contraindications to IUD Use

Copper-containing
Pregnancy or suspicion of pregnancy
Uterine abnormality with distorted uterine cavity
Acute PID, or current behavior suggesting a high risk for PID
Postpartum endometritis or postabortal endometritis in the past 3 months
Known or suspected uterine or cervical malignancy
Genital bleeding of unknown etiology
Mucopurulent cervicitis
Wilson disease
Allergy to any component of ParaGard
A previously placed IUD that has not been removed
Levonorgestrel-releasing
Pregnancy or suspicion of pregnancy
Uterine abnormality with distorted uterine cavity
Acute PID or history of unless there has been a subsequent intrauterine pregnancy
Postpartum endometritis or infected abortion in the past 3 months
Known or suspected uterine or cervical neoplasia
Uterine bleeding of unknown etiology
Untreated acute cervicitis or vaginitis or other lower genital tract infections
Acute liver disease or liver tumor (benign or malignant)
Increased susceptibility to pelvic infection
A previously placed IUD that has not been removed
Hypersensitivity to any component of Mirena
Known or suspected breast cancer or other progestin-sensitive cancer

IUD = intrauterine device; PID = pelvic inflammatory disease.

that of combination oral contraceptive users. Any pelvic infection after 45 to 60 days is considered sexually transmitted and appropriately treated as described in Chapter 3 (p. 115). Unless a tuboovarian abscess has formed, women who develop a genital tract infection with an IUD in place do not need to have the IUD removed. Close clinical reevaluation, which would be warranted for outpatient management of any patient with pelvic inflammatory disease, is warranted (Centers for Disease Control and Prevention, 2015).

Special concerns have arisen for women in whom *Actinomyces* species are identified in the lower genital tract, most commonly during Pap test reporting. Fiorino (1996) noted a 7-percent incidence in the Pap smears of IUD users compared with a 1-percent incidence in nonusers. Currently, in the absence of symptoms, incidental identification of *Actinomyces* species in cytologic specimens has uncertain significance. For an asymptomatic woman, the American College of Obstetricians and Gynecologists (2017) favors expectant management. Other treatment options include oral antibiotics, IUD removal, or antibiotics plus IUD removal. Symptomatic pelvic actinomycosis is rare but tends to be indolent and severe. Treatment is described in Chapter 3 (p. 72).

Young Nulliparas. Young nulliparas, including adolescents, can safely use IUC (American College of Obstetricians and Gynecologists, 2018a; Lohr, 2017). Revised labeling now places no restrictions on IUC use based on parity. A 1-percent lidocaine paracervical block placed immediately before IUD insertion can significantly lower pain scores for nulliparas aged 14 to 22 years (Akers, 2017). However, for all women, misoprostol administration prior to IUD insertion does not enhance insertion success and may increase associated insertional pain (Matthews, 2016; Lathrop, 2013).

Human Immunodeficiency Virus-Infected Women. Intrauterine contraception is appropriate for women with human immunodeficiency virus (HIV) infection who meet other usual criteria for IUD insertion. Neither device type is associated with higher IUD complication rates if used in this population. Moreover, IUDs do not appear to adversely affect viral shedding or antiretroviral therapy efficacy (Tepper, 2016a).

Postabortion or Postpartum Placement. An ideal time to improve successful provision of contraception is immediately following abortion or delivery. For women with an induced or spontaneous first- or second-trimester abortion, IUC can be placed immediately after uterine evacuation. Insertion techniques depend upon uterine size. After first-trimester evacuation, the uterine cavity length seldom exceeds 12 cm. In these instances, the IUD can be placed using the inserter provided in the package. If the uterine cavity is larger, the IUD can be placed using ring forceps with sonographic guidance.

In women for whom an IUD is placed immediately after induced abortion, the repeat induced abortion rate is only one third of the rate of women not choosing immediate IUD placement (Goodman, 2008; Heikinheimo, 2008). As perhaps expected, the risk of IUD expulsion is slightly higher

when placed immediately after abortion or miscarriage, but the advantages of preventing unplanned pregnancies seem to outweigh this (Bednarek, 2011; Fox, 2011; Okusanya, 2014).

Insertion of an IUD immediately following vaginal or cesarean delivery at or near term also has been studied. Moreover, for puerpera at highest risk for future pregnancy complications, the Society for Maternal Fetal Medicine (2019) encourages immediate postpartum LARC insertion for candidates. Placement by hand or by using an instrument has a similar expulsion rate (Xu, 1996).

As with postabortion insertion, expulsion rates by 6 months are higher than those in women whose IUD is placed after complete uterine involution (Lopez, 2015a). In one study, the expulsion rate in the former group was nearly 25 percent (Chen, 2010). Even in these circumstances, however, immediate placement may be beneficial because in some populations up to 40 percent of women do not return for a postpartum clinic visit (Ogburn, 2005). Finally, postpartum placement is category 1 or 2 by the US MEC, that is, its advantages consistently outweigh the risks if puerperal infection is absent (see Table 5-2).

Despite these findings, many choose to delay insertion for several weeks postpartum. Insertion at 2 weeks is quite satisfactory, and in the Parkland System Family Planning Clinics, insertion is scheduled at 6 weeks postpartum to ensure complete uterine involution.

Menstrual Changes. Commonly, IUC may be associated with changes in menstrual patterns. Women who choose the Cu-T 380A are informed that dysmenorrhea and heavier bleeding with menses may develop. Objectively, no clinically significant hemoglobin changes are generally expected (Tepper, 2013). Treatment with a nonsteroidal anti-inflammatory drug (NSAID) will usually diminish the amount of bleeding—even normal amounts—and also relieve dysmenorrhea (Grimes, 2006). Intermenstrual bleeding, however, is typically not improved with these agents (Godfrey, 2013).

With the LNG-IUS, women are counseled to expect irregular spotting for up to 6 months after insertion and thereafter to expect monthly menses to be lighter or even absent. The LNG-IUS device reduces menstrual blood loss and is an effective treatment for some women with heavy menstrual bleeding. This is often associated with improved dysmenorrhea.

Expulsion or Perforation. Approximately 5 percent of women will spontaneously expel their IUD during the first year of use. This is most likely during the first month. Accordingly, a woman is instructed to periodically palpate the marker strings protruding from the cervical os. This can be accomplished by either sitting on the edge of a chair or squatting down and then advancing the middle finger into the vagina until the cervix is reached. Following IUD insertion, women are reappointed for a visit within several weeks, usually after completion of menses. At this meeting, any side effects are addressed, and IUD placement is confirmed by visualizing the marker strings. Some recommend barrier contraception to ensure contraception during this first month. This may be especially desirable if a device has been expelled previously.

The uterus may be perforated either with a uterine sound or with an IUD. Perforations may be clinically apparent or silent. Their frequency depends on operator skill and is estimated to be 1 to 2 per 1000 insertions (Barnett, 2017). In some cases, a partial perforation during insertion results in the IUD later migrating through the uterine wall.

Marker Strings. In some cases, the IUD marker strings may not be palpated or seen during speculum examination. During the investigation, a nonpregnant patient should use alternative contraception. Possibilities are that the device was expelled silently, the device has partially or completely perforated the uterus, the woman is pregnant and the enlarging uterus has drawn the device upward, or the marker strings are temporarily hidden within the endocervical canal. An IUD should not be considered expelled unless it was seen by the patient.

Initially, an endocervical brush or similar instrument can be used to gently draw the string out of the cervical canal. If this is unsuccessful, at least two options are available. After pregnancy has been excluded, the uterine cavity is gently probed using an instrument such as Randall stone forceps or a rod with a hooked end. The strings or device will often be found with this method. If not successful, at this juncture, or possibly as a first choice, transvaginal sonography (TVS) is performed. As described in Chapter 2 (p. 35), 3-dimensional TVS better defines device positioning (Moschos, 2011). If the device is not seen within the uterine cavity or uterine walls, an abdominal radiograph, with or without a uterine sound in place, may localize it. Another option includes office hysteroscopy.

Management decisions depend upon device location and presence of an intrauterine pregnancy. First, a device may penetrate the uterine wall in varying degrees and should be removed. Devices with a predominantly intrauterine location are typically managed by hysteroscopic removal. In contrast, devices that have nearly completely perforated through the uterine wall are more easily removed laparoscopically.

For women with an intraabdominal IUD, an inert-material device located outside the uterus may cause harm, but not universally. Bowel perforations of both large and small bowel as well as bowel fistulas have been reported. In more typical situations, once identified laparoscopically, inert devices can easily be retrieved via laparoscopy. Conversely, an extrauterine copper-bearing device induces intense inflammation with adhesions. Thus, they are more firmly adhered, and laparotomy may become necessary (Balci, 2010). IUDs adhered to the omentum or small bowel may move with these organs from their preoperative radiographic location. Rarely, intraoperative radiography or fluoroscopy may be needed to localize such devices.

In those with pregnancy and an IUD, early pregnancy identification is important. Up to approximately 14 weeks' gestation, the IUD strings may be visible within the cervix, and if seen, they are grasped to remove the entire IUD. This action reduces subsequent complications such as spontaneous abortion, sepsis, and preterm birth (Brahmi, 2012). Tatum and colleagues (1976) reported an abortion rate of 54 percent with the device left in place compared with a rate of 25 percent if it was promptly removed. In another study of Cu-IUDs, outcomes were compared in the two groups of women with and without IUD removal as well as with the general obstetric population. In general, the group of women with an IUD left in place had the worst outcomes.

If pregnancy continuation is desired, IUD removal is recommended. However, if the strings are not visible, attempts to locate and remove the device may result in pregnancy loss. This risk must be weighed against the risk of leaving the device in place. If removal is attempted, TVS can be used. If attempts at removal are followed by evidence for uterine infection, then antibiotics are begun and followed by prompt uterine evacuation.

Ectopic Pregnancy. IUC is effective in preventing all pregnancies. However, the IUC mechanisms of action are more effective in preventing intrauterine implantation. Thus, if IUC fails, a higher proportion of pregnancies are likely to be ectopic (Furlong, 2002).

Insertion Procedures

Before IUD insertion, the FDA requires that a woman be given a brochure detailing the side effects and apparent risks from its use. Timing of insertion influences the ease of placement as well as pregnancy and expulsion rates. When done toward the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, insertion may be easier, and early pregnancy can be excluded. However, insertion is not limited to this time. For a woman who is sure she is not pregnant and does not want to be pregnant, insertion may be carried out any time during the menstrual cycle. Insertion immediately postpartum or postabortion is also feasible and discussed earlier (p. 115).

Prior to insertion, a pelvic examination is completed to identify uterine position and size. Abnormalities are evaluated as they may contraindicate the device. Evidence for infection such as a mucopurulent discharge or significant vaginitis is appropriately treated and resolved before insertion.

For pain management, the most effective method of analgesia has not been established, and patient and provider preference direct selection. Applying lidocaine-prilocaine cream locally or placing paracervical blockade prior to insertion is helpful (Samy, 2019). As noted on page 115, young nulliparas may suffer less pain if a paracervical block with 1-percent lidocaine is given immediately before IUD insertion (Akers, 2017).

Ketorolac or naproxen also has some evidence-based support. But most other NSAIDs, topical lidocaine gel, or misoprostol do not reduce insertion pain (Lopez, 2015b; Samy, 2019).

Immediately prior to initiating the insertion procedure a bimanual examination is performed to assess the size, shape, and position of the uterus. After speculum placement, the cervical surface is cleaned with an antiseptic solution, and a tenaculum is placed on the cervical lip. The uterus is sounded to guide correct depth placement. Specific insertional steps for a given IUD are outlined and illustrated in the prescribing information document accompanying each IUD. If, during insertion, correct IUD positioning is uncertain, then placement may be checked by inspection with sonography. If not positioned completely within the uterus, the device is removed and replaced with a new one. An expelled or partially expelled device should not be reinserted.

Progestin Implants

Contraception can be provided by a progestin-containing device that is implanted subdermally and releases hormone over many years. The devices are coated with a polymer to prevent fibrosis. Several systems have been developed, but only one is available in the United States. The initial implant, the Norplant System, released levonorgestrel from six Silastic rods but was withdrawn from the U.S. market. Supposedly, the silicone-based rods caused ill-defined symptoms that were reversed with removal. A newer two-rod levonorgestrel system, Jadelle, has received FDA approval but is not marketed or distributed in the United States (Sivin, 2002). Sino-implant II is a structurally and pharmacologically similar system to Jadelle. It provides contraception for 5 years and is approved for use by several countries in Asia and Africa (Steiner, 2010).

The implant Nexplanon is currently the only subdermal contraceptive implant marketed in the United States. This single-rod subdermal implant contains 68 mg of the progestin etonogestrel covered by an ethylene vinyl acetate copolymer. Nexplanon has replaced the earlier etonogestrel implant, Implanon.

For Nexplanon, contraception is provided by progestin released continuously to suppress ovulation, thicken cervical mucus, and induce endometrial atrophy. The etonogestrel implant will provide contraception for up to 3 years. At this time, the device is removed, and another rod may be placed within the same incision site. Contraindications for this device are similar to those cited for other progestin-containing methods. Specifically, these include pregnancy, thrombosis or thromboembolic disorders, benign or malignant hepatic tumors, active liver disease, undiagnosed abnormal genital bleeding, or breast cancer (Merck, 2018). Importantly, patients are counseled that Nexplanon causes *irregular bleeding* that does not normalize over time. Thus, women who cannot tolerate unpredictable and irregular spotting or bleeding should select an alternative method.

Nexplanon is inserted subdermally. In 2018, Merck released new recommendations for the location of the Nexplanon insertion. The Nexplanon should be placed overlying the triceps muscle 8 to 10 cm from the medial epicondyle of the humerus and 3 to 5 cm medial to the sulcus (groove) that lies between the biceps and triceps muscles (Merck, 2018). This location is intended to avoid the large blood vessels and nerves lying within and surrounding the sulcus. Subdermal placement is essential, and deeper insertion can risk nerve injury and intravascular migration (Odom, 2017; Rowlands, 2017). Immediately following insertion, the provider and patient should document that the device is palpable beneath the skin.

When Nexplanon is removed, this superficial location allows in-office extraction of the implant. Prior to removal, pressure on the proximal end of the device should elevate its distal tip. An inability to appreciate the distal tip may indicate a deep device. In this instance, removal by a provider with experience and an understanding of upper arm anatomy is preferred (American College of Obstetrics and Gynecology, 2019b; Laumonerie, 2018). For routine cases, following surgical cleansing of the site, a small incision is made large enough to admit hemostat tips. The implant is grasped and removed. If desired, a new rod can be placed at the same time. With the newer recommendations for the location of insertion, the replacement rod may need to be placed in a different location.

If Nexplanon is not palpable, it can be imaged by radiography. Norplant and Jadelle also are radiopaque. This is an advantage compared with Implanon, which was not radiopaque and required sonography with a 10- to 15-MHz sonographic transducer or MR imaging for identification (Shulman, 2006). In the rare event that an etonogestrel implant cannot be palpated or identified radiologically, the manufacturer can be contacted (1-877-888-4231) and arrangements made for etonogestrel level measurement (Merck, 2018).

Permanent Contraception—Sterilization

In 2014, surgical sterilization was one of the most commonly reported forms of contraception in childbearing-aged women in the United States (Guttmacher Institute, 2018). These procedures cannot be tracked accurately because most interval tubal sterilizations and vasectomies are performed in ambulatory surgical centers. However, according to the National Survey of Family Growth, approximately 643,000 female tubal sterilizations are performed annually in the United States (Chan, 2010).

Female Tubal Sterilization

This is usually accomplished by occlusion or division of the fallopian tubes to prevent ovum passage and fertilization. According to the National Health Statistics Report, 25 percent of contracepting women in the United States use this method (Daniels, 2015). Tubal sterilization procedures are performed in conjunction with approximately 7 percent of deliveries (Moniz, 2017). Procedures with this timing are termed *puerperal sterilization*. A tubal sterilization procedure done at a time unrelated to recent pregnancy is called *nonpuerperal tubal sterilization* or *interval sterilization*. Currently, nonpuerperal tubal sterilization is mainly accomplished via laparoscopy.

Tubal Interruption Methods. Three methods, along with their modifications, are used for tubal interruption. These include application of various permanent rings or clips to the fallopian tubes; electrocoagulation of a tubal segment; or ligation with suture material, with or without removal of a tubal segment. In a Cochrane review, Lawrie and colleagues (2016) concluded that all of these are effective in preventing pregnancy.

Electrocoagulation is used for destruction of a segment of tube and can be accomplished with either unipolar or bipolar current. Although unipolar coagulation has the lowest long-term failure rate, it also has the highest serious complication rate. For this reason, of the two, bipolar coagulation is favored by most (American College of Obstetricians and Gynecologists, 2019a).

Mechanical methods of tubal occlusion can be accomplished with: (1) a silicone rubber band such as the Falope Ring or the Tubal Ring, (2) the spring-loaded Hulka-Clemens clip—also known as the Wolf clip, or (3) the silicone-lined titanium Filshie clip. The steps to these procedures are described in Chapter 44 (p. 1019). In a randomized trial of 2746 women, Sokal and associates (2000) compared the Tubal Ring and Filshie clip and reported similar rates of safety and 1-year pregnancy rates of 1.7 per 1000 women. All of these mechanical occlusion methods have favorable long-term success rates.

Suture ligation with tubal segment excision is more often used for puerperal sterilization. Methods include Parkland, Pomeroy, and modified Pomeroy, which are illustrated in Chapter 43 (p. 943).

The type of abdominal entry for sterilization is variable. Laparoscopic tubal ligation is the leading method used in this country for nonpuerperal female sterilization. This is frequently done in an ambulatory surgical setting under general anesthesia, and the woman can be discharged several hours later. Alternatively, some choose minilaparotomy using a 3-cm suprapubic incision. This is especially popular in resource-poor countries. With either laparoscopy or minilaparotomy, major morbidity is rare. Minor morbidity, however, was twice as common with minilaparotomy in a review by Kulier and associates (2004). Finally, the peritoneal cavity can also be entered by colpotomy through the posterior vaginal fornix, although this approach is infrequently used.

Counseling. Indications for this elective procedure for sterilization include a request for sterilization with clear understanding that this is permanent and irreversible. Each woman is counseled regarding all alternative contraceptive options and their efficacy. Many women may also have questions or misunderstanding regarding possible long-term outcomes after female sterilization. As with any operation, surgical risks are assessed, and occasionally the procedure may be contraindicated.

Risk-Reducing Salpingectomy. The Society of Gynecologic Oncology currently recommends consideration of opportunistic bilateral salpingectomy as a preventive measure against serous ovarian and peritoneal cancers among women who are at average risk of ovarian cancer and are undergoing other pelvic surgery or sterilization at the completion of childbearing (Walker, 2015). Most pelvic serous cancers are thought to originate in the distal fallopian tube (Erickson, 2013). And, although currently theoretical, bilateral salpingectomy may lower ovarian cancer rates (Falconer, 2015; Lessard-Anderson, 2014). As discussed in Chapter 35 (p. 736), this may be especially relevant for women at greatest risk for these cancers, namely, women with *BRCA1* or *BRCA2* mutation. If risk-reducing salpingectomy is elected in women with *BRCA* mutations, the pathology requisition form should state this genetic information. This prompts more thorough tubal specimen sectioning and evaluation.

In low-risk women, because the ovarian cancer risk is less than 2 percent, risk-reducing salpingectomy as a sole procedure is likely unwarranted. However, if tubal sterilization is planned, women are counseled regarding risks and benefits of salpingectomy compared with tubal interruption. Data from epidemiologic studies find that tubal interruption offers an approximate 30-percent decline in ovarian cancer rates (Rice, 2012; Sieh, 2013). From similar studies, salpingectomy may reduce the risk by 42 to 78 percent (Gockley, 2018). As another advantage, subsequent tubal surgery may be avoided following total salpingectomy. Retrospective studies have reported that laparoscopic salpingectomy has similar blood loss and complication rate compared with tubal interruption (Kim, 2019; Powell, 2017; Westberg, 2017). However, no prospective studies of sufficient size or duration have yet been done to demonstrate the true risk

and benefit ratio for women. Salpingectomy slightly lengthens operating time and may require additional laparoscopic ports. Lastly, with total salpingectomy for sterilization, few data describe the potential effects on ovarian reserve from blood supply disruption. In one small study comparing the two surgeries, no differences in the antimüllerian hormone level, which is a measure of ovarian reserve, were found (Ganer Herman, 2017; Findley 2013). Thus, women who are at average risk and who are requesting permanent contraception should be fully counselled on the risks and benefits of bilateral salpingectomy versus tubal interruption.

Regret. Invariably, some women will later express regrets regarding sterilization. From a CREST study, Jamieson and coworkers (2002) reported that by 5 years, 7 percent of women undergoing tubal ligation had regrets. This is not limited to female sterilization, as 6 percent of women whose husbands had undergone vasectomy had similar remorse. The cumulative probability of regret within 14 years of sterilization was 20 percent for women aged 30 or younger at sterilization compared with only 6 percent for those older than 30 years (Hillis, 1999).

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed either by surgical reanastomosis or by assisted reproductive techniques. These are technically difficult, expensive, and not always successful. Pregnancy rates vary greatly depending upon age, the amount of tube remaining, and the technology used. Pregnancy rates range from 50 to 90 percent with surgical reversal (Deffieux, 2011). Of note, pregnancies that result after tubal sterilization reanastomosis are at risk to be ectopic.

Method Failure. Reasons for interval tubal sterilization failure are not always apparent, but some have been identified. First, surgical error may occur and likely accounts for 30 to 50 percent of cases. Second, tubal fistula may complicate occlusion methods. Although usually encountered with electrocoagulation procedures, fistulas from inadequate or defective electric current delivery are now less likely because an amp meter is used routinely. In some cases, sterilization failure may follow spontaneous reanastomosis of the tubal segments. With faulty clips, occlusion is incomplete. Last, luteal phase pregnancy may occur and describes the situation in which a woman is already pregnant when the procedure is performed. This can often be avoided by scheduling surgery during the menstrual cycle's follicular phase and by preoperative human chorionic gonadotropin (hCG) testing.

The best estimated overall failure rate with laparoscopic tubal sterilization is from the CREST studies reported by Peterson and coworkers (1999). The reported failure rate was 1.3 percent of 10,685 tubal sterilization surgeries. Shown in Figure 5-4, rates vary for different procedures. And even with the same operation, failure rates vary. For example, with electrocoagulation, if fewer than three tubal sites are coagulated, the 5-year cumulative pregnancy rate approximates 12 per 1000 procedures. However, it is only 3 per 1000 if three or more sites are coagulated. The lifetime increased cumulative failure rates over time are supportive that failures after 1 year are not likely due to technical errors.

With method failure, pregnancies following tubal sterilization have a high incidence of being ectopically implanted compared with the rate in a general gynecologic population.

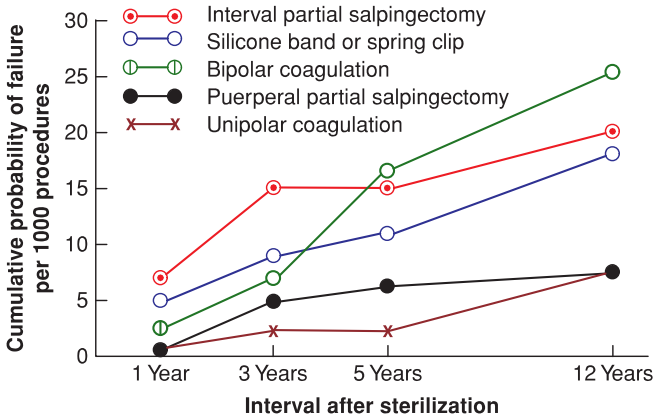

FIGURE 5-4 Data from the U.S. Collaborative Review of Sterilization (CREST) shows the cumulative probability of pregnancy per 1000 procedures by five methods of tubal sterilization.

These rates are especially high following electrocoagulation procedures, in which up to 65 percent of pregnancies are ectopic. With failures following other methods—ring, clip, tubal resection—this percentage is only 10 percent (Peterson, 1999). Importantly, ectopic pregnancy must be excluded when any symptoms of pregnancy develop in a woman who has undergone tubal sterilization.

Other Effects. Several studies have evaluated the risk of heavy menstrual bleeding and intermenstrual bleeding following tubal sterilization, and many report no link (DeStefano, 1985; Shy, 1992). In addition, Peterson and coworkers (2000) compared long-term outcomes of 9514 women who had undergone tubal sterilization with a cohort of 573 women whose partners had undergone vasectomy. Risks for heavy menstrual bleeding, intermenstrual bleeding, and dysmenorrhea were similar in each group. Perhaps unexpectedly, women who had undergone sterilization had *decreased* duration and volume of menstrual flow, they reported *less* dysmenorrhea, but they had an *increased* incidence of cycle irregularity.

Other long-term effects have also been studied. It is controversial whether risks for subsequent hysterectomy are elevated (Pati, 2000). In a CREST surveillance study, Hillis and associates (1997) reported that 17 percent of women undergoing tubal sterilization subsequently had undergone hysterectomy by 14 years. Although they did not compare this incidence with a control cohort, the indications for hysterectomy were similar to those for nonsterilized women who had undergone a hysterectomy. Women are highly unlikely to develop salpingitis following sterilization (Levgur, 2000).

Some psychological sequelae of sterilization were evaluated in a CREST study by Costello and associates (2002). Tubal ligation did not change sexual interest or pleasure in 80 percent of women. In the remaining 20 percent who reported a change, 80 percent described the changes to be positive.

Transcervical Sterilization

Sterilization may theoretically be completed using a transcervical approach to reach the tubal ostia. However, no methods using this approach are currently approved in the United States.

FIGURE 5-5 Microinsert used in the Essure Permanent Birth Control System.

Mechanical methods employ insertion of a device into the proximal fallopian tubes via hysteroscopy. Both the Essure system and the Adiana Permanent Contraception system have been removed from the U.S. market.

The Essure Permanent Birth Control System consists of a microinsert made of a stainless steel inner coil that is enclosed in polyester fibers. These fibers are surrounded by an expandable outer coil made of *nitinol*—a nickel and titanium alloy used in coronary artery stents (Fig. 5-5). Fibroblastic proliferation within the fibers causes tubal occlusion. Essure contraceptive failure rates range from <1 percent to 5 percent (Gariepy, 2014; Munro, 2014).

Chronic pelvic pain after hysteroscopic sterilization may develop in 2 to 6 percent of those with inserts (Chudnoff, 2015; Kamencic, 2016; Yunker, 2015). Pain may stem from tubal perforation, device migration, or the device itself (Adelman, 2014). For those desiring removal, one method is described in Chapter 44 (p. 1024). Importantly, device removal is not curative in all symptomatic patients (Clark, 2017; Maassen, 2019).

As with all sterilization procedures, Essure placement should be considered permanent. The success rate of subsequent spontaneous pregnancy after microsurgery tubal reversal ranges between 0 and 36 percent (Fernandez, 2014; Monteith, 2014).

Chemical agents may also be placed into the uterine cavity or tubal ostia to incite an inflammatory response to cause tubal occlusion. A method that has been used worldwide in more than 100,000 women consists of using an IUD-type inserter to place quinacrine pellets. It is effective, especially considering its simplicity. Pregnancy rates reported by Sokal and colleagues (2008) were 1 and 12 percent at 1 and 10 years, respectively. The World Health Organization (WHO) (2009) recommended against its use because of carcinogenesis concerns. Evidence is contradictory, and some consider it a potential option for resource-poor countries (Lippes, 2015).

Hysterectomy

For a woman with uterine or other pelvic disease for which hysterectomy may be indicated, this may be the ideal form of sterilization.

Male Sterilization

Vasectomy is performed for approximately one-half million men each year in the United States (Ostrowski, 2018). The office procedure is done with local analgesia and usually takes ≤20 minutes to complete. As illustrated in Figure 5-6, a small incision is made in the scrotum, and the lumen of the vas deferens is disrupted to block sperm traveling from the testes. Vasectomy is highly effective and has a failure rate <1 percent (Michielsen, 2010). Causes include failure from unprotected intercourse too soon after vasectomy, incomplete vas deferens occlusion, or recanalization following suitable separation.

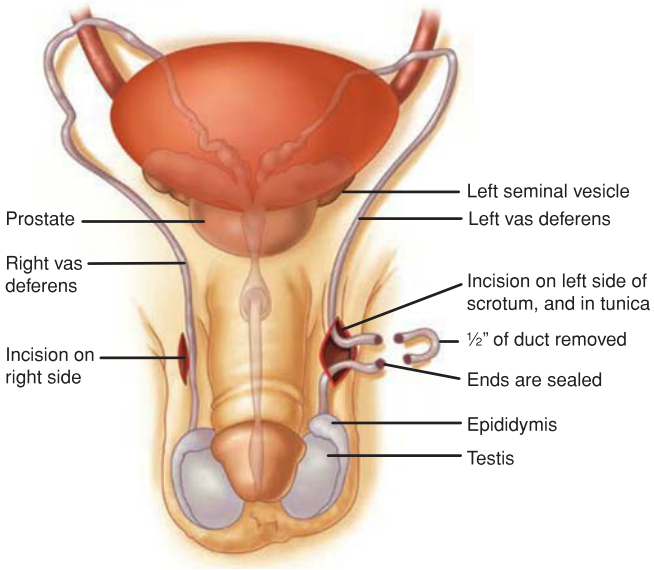

FIGURE 5-6 Vasectomy. On the left, the incision site is shown. On the right, a portion of the vas deferens has been excised.

Sterility following vasectomy is not immediate nor is its onset reliably predictable. The time until complete expulsion of sperm stored distal to the vas deferens interruption is variable and requires approximately 3 months or 20 ejaculations. Thus, another form of contraception is used until azoospermia is documented. Although most recommend that semen be analyzed until two consecutive sperm counts are zero, Bradshaw and coworkers (2001) reported that a single azoospermic semen analysis is sufficient.

Fertility Restoration. After vasectomy, fertility may be restored either by surgical reanastomosis techniques or by sperm retrieval from the testis. Surgical reversal techniques and perioperative evaluation have been reviewed by the American Society for Reproductive Medicine (2008). Sperm retrieval combined with in vitro fertilization techniques avoids such reversal surgeries and is described in Chapter 21 (p. 464). From their review, Shridharani and Sandlow (2010) concluded that microsurgical reversal is cost effective, but comparative trials with sperm retrieval methods are needed.

Long-Term Effects. Regret of sterilization was discussed on page 119. Other than this, long-term consequences are rare (Amundsen, 2004). However, because antibodies directed at spermatozoa frequently develop in these men, there were initial concerns that these might cause systemic disease. Putative risks were analyzed by Köhler and coworkers (2009) and include cardiovascular disease, immune-complex disorders, psychological changes, male genital cancers, and frontotemporal dementia. Their findings and those of others are not convincing for a greater risk of cardiovascular disease or accelerated atherogenesis from vasectomy (Schwingl, 2000). Moreover, rates of testicular

or prostate cancers do not appear increased with this procedure (Holt, 2008; Köhler, 2009).

SECOND-TIER CONTRACEPTIVE METHODS

Contraceptives considered to be *very effective* are the hormone-containing preparations that include combination oral contraceptives (COCs), progestin-only contraceptive pills, and contraceptives with estrogens and/or progestins that are made systemically available by injection, transdermal patch, or intravaginal ring. When used as intended, these methods are effective, however, their efficacy is user dependent. Thus, *typical use* considers each woman's compliance with taking a daily pill, changing transdermal patches or rings, or presenting for an injection (see Table 5-1). Such "real world" use significantly diminishes their efficacy, and for women in the United States, these contraceptives have a first-year pregnancy rate of 4 to 7 per 100 users (Trussell, 2018).

Combined Hormonal Contraceptives

These are contraceptives that contain an estrogen and a progestin. As such, several underlying conditions are considered contraindications (Table 5-5). CHCs are available in the United States in three formats—combination oral contraceptive pills, the transdermal patch, and the intravaginal contraceptive ring. Because of limited data for the transdermal and transvaginal methods relative to that for COCs, their use is usually considered along with the combined oral form.

Pharmacology

CHCs provide multiple contraceptive actions. The most important is ovulation inhibition by suppression of hypothalamic gonadotropin-releasing hormone, which prevents pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Estrogens suppress FSH release and stabilize the endometrium to prevent intermenstrual bleeding—referred to as *breakthrough bleeding* in this setting. Progestins inhibit ovulation by suppressing LH, they thicken cervical mucus to restrict sperm passage, and they render the endometrium unfavorable for implantation. Thus, CHCs have contraceptive effects from both hormones and, when taken daily for 3 out of every 4 weeks, provide virtually absolute protection against conception.

Until recently, only two estrogens were available for use in oral contraceptives in the United States. These were *ethinyl estradiol* and its less commonly used 3-methyl ether, *mestranol* (Table 5-6). In 2010, a third estrogen compound—*estradiol valerate*—was approved by the FDA. Most currently available progestins are *19-nortestosterone* derivatives. However, drospirenone is a spironolactone analogue, and the dose of drospirenone in COCs currently marketed has properties similar to 25 mg of this diuretic (Seeger, 2007). It displays antiandrogenic activity, and its antimineralocorticoid properties may, in theory, cause potassium retention, leading to hyperkalemia. Thus, drospirenone is not prescribed for those with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, monitoring of serum potassium levels is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention (Bayer HealthCare Pharmaceuticals, 2012). Several studies have shown improvement in symptoms for women with premenstrual dysphoric disorder (PMDD) who use a drospirenone-containing COC, Yaz (Lopez, 2012; Yonkers, 2005). For this pill, the FDA has approved its indications to include treatment of PMDD and moderate acne vulgaris for women requesting oral contraception.

TABLE 5-5. Contraindications to the Use of Combination Oral Contraceptives

Pregnancy
Uncontrolled hypertension
Smokers older than 35 years
Diabetes with vascular involvement
Cerebrovascular or coronary artery disease
Migraines with associated focal neurologic deficits
Thrombophlebitis or thromboembolic disorders
History of deep-vein thrombophlebitis or thrombotic disorders
Thrombogenic heart arrhythmias or thrombogenic cardiac valvulopathies
Undiagnosed abnormal genital bleeding
Known or suspected breast carcinoma
Cholestatic jaundice of pregnancy or jaundice with pill use
Hepatic adenomas or carcinomas or active liver disease with abnormal liver function
Endometrial cancer or other known or suspected estrogen-dependent neoplasia

TABLE 5-6. Estrogen and Progestins Used in FDA-Approved Oral Contraceptive Pills

Combination Pills	
Estrogen Type (pill dose)	**Paired Progestin[a]**
Ethinyl estradiol 10 μg	Norethindrone acetate
Ethinyl estradiol 20 μg	Desogestrel Drospirenone Levonorgestrel Norethindrone acetate
Ethinyl estradiol 25 μg	Desogestrel Norgestimate
Ethinyl estradiol 30–35 μg	Desogestrel Drospirenone Ethynodiol diacetate Levonorgestrel Norethindrone Norethindrone acetate Norgestimate Norgestrel
Ethinyl estradiol 50 μg	Ethynodiol diacetate Norgestrel
Estradiol valerate 2 mg	Dienogest
Mestranol 50 μg	Norethindrone

[a]Progestins are listed alphabetically.
FDA = Food and Drug Administration.

Progestins were initially selected for their progestational potency. However, they are often compared, marketed, and prescribed based on their presumed estrogenic, antiestrogenic, and androgenic effects. However, the doses of progestins used in combined contraceptive formulations are so low that none of these purported negative side effects are actually manifested clinically. In fact, an important effect of CHCs is enhanced production of sex hormone–binding globulin (SHBG) by the liver and production is promoted mostly by the estrogen component of CHCs. Elevated SHBG levels lower serum free testosterone levels and thereby limit 5α-reductase, the enzyme necessary to convert testosterone to its active form, dihydrotestosterone. For this reason, progestins can be expected to have salutary effects on androgen-related conditions such as acne (Rosen, 2003; Thorneycroft, 1999).

Combined Oral Contraceptive Pills

Formulations. COCs are marketed in a bewildering variety. Currently, the daily estrogen content in most COCs varies from 20 to 50 μg of ethinyl estradiol, and most pills contain 35 μg or less (see Table 5-6). Of note, in 2011, the FDA approved the first pill containing only 10 μg of ethinyl *estradiol—Lo Loestrin Fe*. For current formulations, the lowest acceptable dose is governed by the ability to prevent unacceptable breakthrough bleeding.

With COCs, the progestin dose can be constant throughout the cycle—*monophasic pills*—but the dose frequently is varied—*biphasic* and *triphasic pills* (Fig. 5-7). In some of these, the estrogen dose is also varied during the cycle. Such *multiphasic pills* were developed to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning with a low dose of progestin and raising it later in the cycle. Theoretically, the lower total dose minimizes the intensity of progestin-induced metabolic changes and adverse side effects. Disadvantages of multiphasic formulations include confusion caused by the multicolored pills, and some brands contain five colors. Also, breakthrough bleeding or spotting rates are likely higher compared with monophasic pills (Woods, 1992).

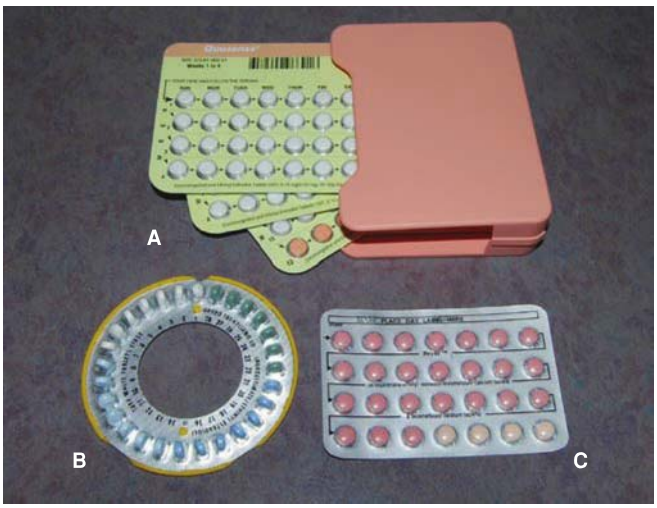

FIGURE 5-7 Various combined oral contraceptive (COC) pills. **A.** Extended-use COCs. Each of the three sequential cards of pills is taken. Placebo pills (*peach*) are found in the bottom card. **B.** 21/7 triphasic COCs. Active pills are taken for 3 weeks and are followed by seven placebo pills (*green*). With triphasic pills, the combination of estrogen and progestin varies with color changes, in this case, from white to blue to dark blue. **C.** 24/4 monophasic COCs. Monophasic pills contain a constant dose of estrogen and progestin throughout the pill pack. With 24/4 dosing regimens, the number of placebo pills is decreased to four.

In a few COCs, inert placebo pills have been replaced by tablets containing iron. These have the suffix Fe added to their name. In addition, Beyaz has a form of folate—levomefolate calcium—within both its active and placebo pills.

Administration. Women may begin COCs on a *quick start* method. With this, pills are started on any day of the cycle, commonly the day prescribed. This approach improves short-term compliance (Westhoff, 2002, 2007a). A more traditional schedule—the *Sunday start*—requires pill initiation on the first Sunday following the onset of menses. If menses begin on a Sunday, pills are started that day. Last, both Sunday start and quick start methods require use of an additional method for 1 week to protect against conception, unless the pill is started on the first day of a menstrual cycle, in which case an additional contraceptive method is unnecessary.

To obtain maximum efficacy and promote regular use, most manufacturers offer dispensers that provide 21 sequential color-coded tablets containing hormones, followed by seven inert tablets of another color (see Fig. 5-7B). Some newer, lower-dose pill regimens continue active hormones for 24 days, followed by 4 days of inert pills (see Fig. 5-7C). The goal of these 24/4 regimens is to improve the efficacy of very low-dose COCs. Importantly, for maximum contraceptive efficiency, each woman should adopt an effective scheme for ensuring consistent daily or nightly self-administration.

During COC use, if one dose is missed, conception is unlikely with higher-dose monophasic COCs. When this is recognized, taking that day's pill plus the missed pill will minimize breakthrough bleeding. The remainder of the pill pack is then completed with one pill taken daily.

If several doses are missed, or if a dose is missed with the lower-dose pills, then two pills are taken but an effective barrier technique is added for the subsequent 7 days. The remainder of the pack is completed with one pill taken daily. Alternatively, a new pack can be started and a barrier method added as additional contraception for a week. With any scenario of missed pills, if withdrawal bleeding does not occur during the placebo pills, the pills are continued, but the woman should seek medical attention to exclude pregnancy. Fortunately, CHCs are not teratogenic if taken accidentally during early pregnancy (Charlton, 2016).

Transdermal System

One transdermal system is available in the United States—*Ortho Evra patch*. The patch has an inner layer with an adhesive and hormone matrix and an outer water-resistant layer. The patch is applied to the buttocks, upper outer arm, lower abdomen, or upper torso but avoids the breasts. It delivers daily a dose of 150 μg of the progestin norelgestromin and 20 μg of ethinyl estradiol. A new patch is applied each week for 3 weeks, followed by a patch-free week to allow withdrawal bleeding.

Initial concerns questioned the patch efficacy in obese women. However, evidence informing use of the transdermal patch among

women with a body mass index (BMI) ≥25 is low quality and limited (Lopez, 2016). Currently, no recommendations suggest a transdermal patch dosing change for women with a BMI >30 (Curtis, 2016). The patch's other metabolic and physiologic effects mirror those seen with low-dose COCs, with the caveat that accumulated experience is limited. The patch is suitable for women who prefer weekly applications to daily dosing and who meet the other criteria for CHC administration.

Another concern was that CHC delivered by the patch may be associated with a higher risk for VTE and other vascular complications. This followed reports that patch use was associated with greater hepatic synthesis of procoagulants compared with COC or vaginal ring use (Jensen, 2008; White, 2006). Although peak serum estrogen levels were lower with patch versus COC use, total exposure was greater—a relatively greater net estrogen effect (Kluft, 2008; van den Heuvel, 2005). Despite lack of a convincing clinical association, the FDA in 2008 ordered patch labeling to state that users *may* be at higher risk for developing VTE. To date, conclusive evidence for greater morbidity with the patch compared with other CHC forms is lacking (Jick, 2010; Tepper, 2017).

Transvaginal Ring

One intravaginal hormonal contraceptive is available in the United States—*NuvaRing*. It is a flexible polymer ring with a 54-mm outer diameter and a 50-mm inner diameter (Fig. 5-8). Its core releases a daily dose of 15 μg ethinyl estradiol and 120 μg of the progestin etonogestrel. These doses effectively inhibit ovulation, and the failure rate is reported to be 0.65 pregnancies per 100 woman-years (Mulders, 2001; Roumen, 2001).

Prior to dispensing, the pharmacy must keep rings refrigerated. Once dispensed, their shelf life is 4 months. The ring is initially inserted within 5 days after the onset of menses. After 3 weeks, it is removed for 1 week to allow withdrawal bleeding. Then, a new ring is inserted. Breakthrough bleeding is uncommon. Up to 20 percent of women and 35 percent of men reported being able to feel the ring during intercourse. If bothersome, the ring may be removed for coitus, but it should be replaced within 3 hours.

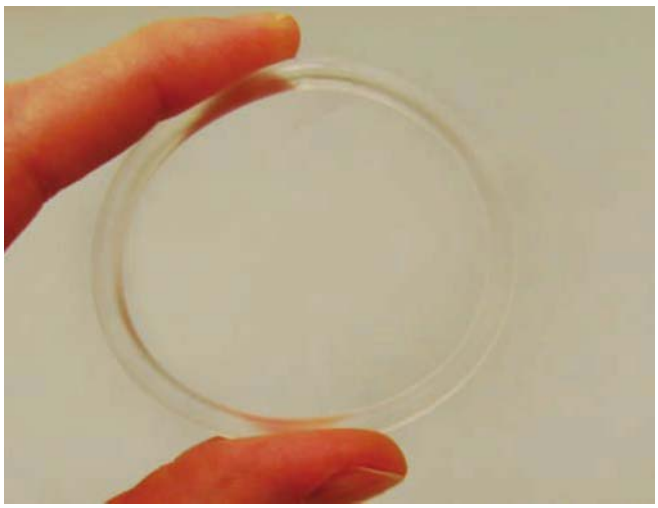

FIGURE 5-8 Estrogen- and progestin-releasing vaginal contraceptive ring.

Extended-Cycle Contraception

The use of CHCs continuously for more than 28 days has become increasingly popular. Benefits include fewer episodes of cyclic bleeding, diminished menstrual symptoms, and lower costs. Several prepackaged formulations are available, but extended-cycle contraception can also be achieved in other ways. Namely, the standard 21- or 28-day COC packs, with the placebo pills discarded, can be used continuously. Also, either the transdermal patch or the vaginal ring can be used without the 1-week hormone-free interval.

Several factors unique to extended-cycle CHCs are important. Some of these are shared with continuous progestin contraceptive methods such as implants or injections. The principal change is loss of menstrual normalcy that manifests as less frequent, lighter, and generally unpredictable bleeding episodes. For example, amenorrhea of 6 months or more is reported to affect 8 to 63 percent of extended-cycle users. Although considered a benefit by most women, it is far from a guaranteed one. More often, women have fewer bleeding episodes per month. This allows repair of associated anemia in those who had heavy menstrual bleeding prior to extended-cycle use.

However, these characteristics also render some women reluctant to use this method, as it may be considered "unnatural" to miss monthly menses. Some are concerned that amenorrhea may be a sign of pregnancy, may diminish future fertility, or may increase endometrial neoplasia risk. Rather, findings support a *lower* risk for endometrial malignancy with cyclic CHC use. Thus on a biological basis, it seems reasonable to conclude that this protective effect would also apply to continuous CHC use. Moreover, hypothalamic-pituitary-ovarian suppression is greater with continuous use and reduces the possibility of escape ovulation caused by delayed start of a new contraceptive cycle.

Drug Interactions

Interactions between CHCs and various other medications take two forms. First, hormonal contraceptives may interfere with the actions of some drugs shown in Table 5-7. As an example, levels of the anticonvulsant lamotrigine are typically lowered by CHCs (p. 126).

In contrast, some drugs shown in Table 5-8 may diminish the effectiveness of CHCs. In many cases, genes coding for cytochrome oxidase system enzymes are either stimulated or suppressed. Notably, antibiotics other than rifampin do not lower clinical efficacy of COCs (Simmons, 2018). Also, most antiretroviral regimens for treatment of human immunodeficiency infection (HIV) are compatible with CHCs. Of exceptions, efavirenz may lower CHC efficacy, whereas CHCs may diminish fosamprenavir effectiveness (Curtis, 2016; Nanda, 2017). For other HIV agents, similar potential interactions can be researched at the University of California, San Francisco HIV InSite website: http://hivinsite.ucsf.edu/insite?page=ar-00-02.

These interactions often require that the dose of contraceptive or that of the other drug be adjusted to ensure efficacy. Alternatively, choosing another contraceptive method may be preferable.

Use with Medical Disorders

A summary of health benefits associated with combination hormonal contraceptives is found in Table 5-9. Despite this,

TABLE 5-7. Drugs Affected by Combination Oral Contraceptives (COCs)

Interacting Drug	Documentation	Management
Analgesics		
Acetaminophen	Adequate	Possible dose increase needed
Aspirin	Probable	Possible dose increase needed
Meperidine	Suspected	Possible dose decrease needed
Morphine	Probable	Possible dose increase needed
Anticoagulants		
Dicumarol, warfarin	Controversial	
Antidepressants		
Imipramine	Suspected	Reduce dosage about a third
Tranquilizers		
Diazepam, alprazolam	Suspected	Reduce dose
Temazepam	Possible	Possible dose increase needed
Other benzodiazepines	Suspected	Observe for increased effect
Antiinflammatories		
Corticosteroids	Adequate	Watch for increased effect, decrease dose accordingly
Bronchodilators		
Aminophylline, theophylline	Adequate	Reduce starting dose by a third
Antihypertensives		
Cyclopenthiazide	Adequate	Increase dose
Metoprolol	Suspected	Possible dose decrease needed
Other		
Troleandomycin	Suspected liver damage	Avoid
Cyclosporine	Possible	May use smaller dose
Antiretrovirals	Variable	See manufacturer or other[a]
Lamotrigine	Adequate	With monotherapy or when given with drugs that are not known to alter lamotrigine levels, then avoid COCs

COC = combination oral contraceptives; EE = ethinyl estradiol.
Summarized from Back, 1980; Berry-Bibee, 2016; Curtis, 2016; Gaffield, 2011; Nanda, 2017; Reimers, 2015; Van Dijke, 1984.

interactions of CHCs with some chronic medical disorders may constitute relative or absolute contraindication to CHC use. These are described in the following sections.

Obese and Overweight Women. In general, CHCs are highly effective in obese women (Lopez, 2016). However,

TABLE 5-9. Some Benefits of Combination Estrogen Plus Progestin Oral Contraceptives

Acne improvement
Increased bone density
Prevention of atherogenesis
Fewer premenstrual complaints
Inhibition of hirsutism progression
Decreased risk of ectopic pregnancy
Decreased activity of rheumatoid arthritis
Reduced menstrual blood loss and anemia
Reduction in various benign breast diseases
Improved dysmenorrhea from endometriosis
Decreased risk of endometrial and ovarian cancer
Decreased incidence and severity of acute salpingitis

obesity may result in altered pharmacokinetics of some CHC methods. That said, data regarding overweight women are conflicting regarding greater pregnancy risk due to decreased CHC efficacy from lowered bioavailability (Brunner, 2005; Edelman, 2009; Holt, 2005; Westhoff, 2010). Importantly, in some women, obesity may be synergistic with other conditions, described next, that may render CHCs a less optimal contraceptive method.

Excessive weight gain is a concern with use of any hormonal contraceptive. Gallo and associates (2014) again concluded in their review that available evidence was insufficient to determine the influence of CHCs on weight gain, although no large effect was obvious.

Diabetes Mellitus. Higher-dose COCs were associated with insulin antagonistic properties, particularly those mediated by progestins. However, with current low-dose CHCs, these concerns have been mitigated. In healthy women, large, long-term prospective studies have found that COCs do not increase the risk for diabetes (Rimm, 1992). Moreover, these agents do not appear to raise the risk for overt diabetes in women with prior gestational diabetes (Kjos, 1998). Last, use of these contraceptives is approved for nonsmoking diabetic women who are younger than 35 years and who have no associated vascular disease (American College of Obstetricians and Gynecologists, 2019d).

Cardiovascular Disease. In general, severe cardiovascular disorders limit the use of CHCs. For less severe disorders, however, current formulations do not raise associated risks.

First, low-dose CHCs do not appreciably raise the absolute risk of clinically significant hypertension (Chasan-Taber, 1996). However, it is common practice for patients to return 8 to 12 weeks following CHC initiation for evaluation of blood pressure and other symptoms. For those with already established chronic hypertension, CHC use is permissible in those with well-controlled, otherwise uncomplicated hypertension (American College of Obstetricians and Gynecologists, 2019d). Severe forms of hypertension, especially those with end-organ involvement, usually preclude CHC use.

Women who have had a documented *myocardial infarction* should not be given CHCs. That said, these contraceptives do not elevate the de novo risk for myocardial ischemia in nonsmoking women younger than 35 years (Margolis, 2007; Mishell, 2000; World Health Organization, 1997). Smoking by itself, however, is a potent risk factor for ischemic heart disease, and CHCs used after age 35 years act synergistically to enhance this risk.

Cerebrovascular Disorders. Women who have had either an *ischemic* or *hemorrhagic stroke* should not use CHCs. But the incidence in nonsmoking young women is low, and use of CHCs does not raise the risk for either type of stroke in these women (World Health Organization, 1996). Stroke is more commonly encountered in those who smoke, have hypertension, or have migraine headaches with visual aura *and* who use CHCs (MacClellan, 2007).

Migraine headaches may be a risk factor for strokes in some young women. One systematic review reported that women using COCs who had migraine headaches had a two- to fourfold greater risk for stroke compared with nonusers (Tepper, 2016c). The American College of Obstetricians and Gynecologists (2019d), because the absolute risk is low, has concluded that CHCs may be considered for young nonsmoking women who have migraine headaches without focal neurologic changes. For many of these women, an intrauterine contraceptive method or a progestin-only pill may be more appropriate.

Venous Thromboembolism. Early in CHC history, it was apparent that *deep-vein thrombosis* and *pulmonary embolism* risks were significantly elevated in women who used these contraceptives (Realini, 1985). These risks were found to be estrogen-dose related and have been appreciably lowered with evolution of low-dose formulations that contain only 20 to 35 μg of ethinyl estradiol (Westhoff, 1998). Of note, a possible increased VTE risk with drospirenone-containing COCs has been shown in two studies. The FDA has encouraged an assessment of benefits and of VTE risks in users of these pills (Food and Drug Administration, 2012; Jick, 2011; Parkin, 2011).

Mishell and coworkers (2000) concluded that VTE risk is three- to fourfold higher in current COC users compared with nonusers. However, the risk without contraception is low—approximately 1 per 10,000 woman years—and thus the incidence with CHCs is only 3 to 4 per 10,000 woman years. Importantly, these CHC-enhanced risks appear to dissipate rapidly once contraceptive treatment is discontinued. And, of equal importance, these VTE risks are still lower than those estimated during pregnancy, which has an incidence of 5 to 6 per 10,000 woman years.

Several cofactors raise the incidence of VTE in women using estrogen-containing contraceptives or those who are pregnant or postpartum. These include one or more of the many *thrombophilias,* which include *protein C* or *S deficiency* or *factor V Leiden mutation* (Chap. 39, p. 834) (Mohllajee, 2006). Other factors that raise VTE risks are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Pomp, 2007, 2008).

Older studies indicated a twofold higher risk for *perioperative VTE* in CHC users (Robinson, 1991). Data are lacking with the low-dose formulations currently used, and thus the American College of Obstetricians and Gynecologists (2019d) recommends balancing VTE risks against those of unintended pregnancy during the 4 to 6 weeks required preoperatively for thrombogenic effects of CHCs to dissipate. For women undergoing major surgery with prolonged immobility, CHCs are halted perioperatively.

Systemic Lupus Erythematosus. The use of CHCs in women with otherwise uncomplicated systemic lupus erythematosus (SLE) has been the "poster child" for evidence-based clinical research. In the past, and with good reason, CHCs were contraindicated in women with SLE. This was because of their underlying high risk to develop venous and arterial thrombosis along with the thrombogenic effects of older high-dose COC pills. The safety of the low-dose modern COCs in many women with SLE was shown in two randomized trials (Petri, 2005; Sánchez-Guerrero, 2005). Importantly, CHCs are not appropriate in women with SLE who have positive testing for antiphospholipid antibodies or have other known contraindications to CHC use. Affected women with these antibodies have elevated clotting risks.

Seizure Disorders. Approximately 1 million women of reproductive age in the United States are diagnosed with some form of epilepsy. As shown in Tables 5-7 and 5-8, metabolism and clearance of some CHCs are appreciably altered by some, but not all, of the commonly used anticonvulsants. One mechanism with several antiepileptic drugs is potent induction of cytochrome P450 system enzymes. In turn, this boosts contraceptive steroid metabolism, and serum levels of these decrease by as much as half (American College of Obstetricians and Gynecologists, 2019d; Zupanc, 2006).

These metabolic interactions usually do not result in increased seizure activity. One possible exception is combined use of CHCs and monotherapy with the anticonvulsant lamotrigine. Serum anticonvulsant levels decline by up to 50 percent, which may raise seizure risks (Gaffield, 2011).

Evidence-based guidelines for use of contraceptives by women with epilepsy are listed in the US MEC. Use of CHCs in epileptic women is rated as category 1. However, CHCs used concurrently with some anticonvulsants may reduce contraceptive or anticonvulsant effectiveness. Thus, epileptic women using cytochrome P450 enhancing anticonvulsants are counseled regarding alternate contraceptive methods if feasible. If not, a COC containing at least 30 μg of ethinyl estradiol should be used. For those using lamotrigine monotherapy, CHCs are not recommended.

Although they are not CHCs, progestin-only containing preparations also are affected by use of anticonvulsants that induce the cytochrome P450 enzyme system. These result in decreased serum progestin levels and lower rates of effective ovulation suppression and pose an unacceptable risk of unplanned pregnancy.

Liver Disease. Both estrogens and progestins have known effects on hepatic function. Cholestasis and cholestatic jaundice, which develop more commonly in pregnancy, also are infrequently induced by CHC use. Because susceptibility is likely due to an inherited gene mutation of bilirubin transport, cholestasis with CHCs is more likely in women also affected during a pregnancy. Discontinuing CHCs typically resolves symptoms. Whether these cholestatic effects of CHCs also raise risks for subsequent cholelithiasis and cholecystectomy is unclear. Any elevated risk is likely to be small, and the known effects of increasing parity on gallbladder disease must also be considered.

Regarding women with viral hepatitis or cirrhosis, the WHO has provided recommendations (Kapp, 2009b). For women who have active hepatitis, CHCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking CHCs. Use of progestin-only contraception in these women is not restricted. With cirrhosis, mild compensated disease does not limit the use of CHCs or progestin-only methods. However, in those with severe decompensated disease, all hormonal types are avoided.

Neoplastic Diseases. Stimulatory effects of sex steroids on some cancers are a concern. It would appear, however, that overall these hormones do not *cause* cancer (Hannaford, 2007). A report from the Collaborative Group on Epidemiological Studies of Ovarian Cancer (2008) verified earlier studies that showed a protective effect against endometrial and ovarian cancers (Cancer and Steroid Hormone Study, 1987a,b). However, this protection wanes as duration from pill discontinuance lengthens (Tworoger, 2007). Reports concerning possible increased risks for premalignant and malignant changes of the liver, cervix, and breast are conflicting and are presented next.

First, *hepatic focal nodular hyperplasia* and *benign hepatic adenomas* were previously linked with older higher-dose estrogen-containing COCs. However, studies that evaluated women taking contemporary low-dose COCs reported no such association (Hannaford, 1997; Heinemann, 1998). Similarly, earlier correlations between CHCs and hepatocellular carcinoma have been refuted (Maheshwari, 2007; World Health Organization, 1989). For women with known tumors, COCs may be used in those with focal nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009a).

Second, *cervical dysplasia* and *cervical cancer* rates are higher in COC users. These risks increase with duration of use. But, according to the International Collaboration of Epidemiological Studies of Cervical Cancer (2007), if COC use is discontinued, by 10 years the risk becomes comparable with that of never-users. The reasons for this neoplasia risk are speculative and may be related to more frequent human papillomavirus (HPV) exposure because of decreased use of barrier methods. It may also be related to the more frequent cytologic screening that COC users may have. Moreover, COCs may favor persistence of HPV infection and HPV oncogene expression (de Villiers, 2003). Importantly, if cervical dysplasia is treated, the recurrence rate is not higher in CHC users.

Last, *breast cancer* is stimulated by female sex steroid hormones, but it is still unclear whether CHCs have an adverse effect on tumor growth or development. The Collaborative Group on Hormonal Factors in Breast Cancer (1996) analyzed data from studies that included more than 53,000 women with breast cancer and 100,000 nonaffected women. They found a significant 1.24-fold higher risk for current COC users. This risk declined to 1.16 for those 1 to 4 years after discontinuing COCs and 1.07 for those at 5 to 9 years. The risks were not influenced by age at first use, duration of use, family history of breast cancer, first use prior to pregnancy, or the dose or type of hormone used. This lack of correlation serves to question any causal role of COCs in breast tumorigenesis.

The Collaborative Group investigators also found that COC-associated tumors tended to be to be less aggressive and that cancers were detected at earlier stages. They suggested that the increased cancer diagnosis may have been because of more intensive surveillance among users. In a case-control study—4575 cases and 4682 controls—no relationship was found with either current or past COC use and breast cancer (Marchbanks, 2002). Finally, women heterozygous for *BRCA1* or *BRCA2* gene mutations do not have a higher incidence of breast or ovarian cancer with COC use (Brohet, 2007). With regard to benign breast disease, Vessey and Yeates (2007) reported that COC use apparently *lowered* the relative risk.

Progestin-Only Contraceptives

Contraceptives that contain only a progestin were developed to obviate the unwanted side effects of estrogens. Progestins can

be delivered by several routes that include tablets, injections, intrauterine devices, and subdermal implants.

Progestin-Only Pills

Also called *mini-pills*, POPs are taken daily. They do not reliably inhibit ovulation, but instead thicken cervical mucus and decidualize and atrophy the endometrium. Because mucus changes do not persist beyond 24 hours, to be maximally effective, a pill is ideally taken at the same time daily. Their use has not achieved widespread popularity because of a much higher incidence of irregular bleeding and a slightly higher pregnancy rate than that seen with CHCs (see Table 5-1).

POPs have minimal if any effect on carbohydrate metabolism and coagulation factors. They do not cause or exacerbate hypertension and thus may be ideal for some women at higher risk for other cardiovascular complications. Because they do not impair milk production, POPs are suitable for lactating women. When used in combination with breastfeeding, POPs are virtually 100-percent effective for up to 6 months (Betrabet, 1987; Shikary, 1987). POPs should not be taken by women with unexplained uterine bleeding, breast cancer, hepatic neoplasms, pregnancy, or active severe liver disease (Janssen Pharmaceuticals, 2017).

Compliance is essential to POP use. If a pill is taken even 4 hours late, an additional form of contraception must be used for the next 48 hours. This may contribute to another major drawback, which is a higher risk for contraceptive failure compared with CHCs. Moreover, with failure, the proportion of pregnancies that are ectopic is increased (Sivin, 1991).

Another disadvantage is irregular uterine bleeding. This may be characterized by amenorrhea, intermenstrual bleeding, or prolonged heavy menstrual bleeding. As with other progestin-containing contraceptive methods, functional ovarian cysts develop with a greater frequency, although they usually do not require intervention (Hidalgo, 2006; Inki, 2002).

Injectable Progestins

Formulations. Three injectable depot progesterone preparations are used worldwide. This method is popular in the United States and is used by approximately 5 percent of women choosing a contraceptive (Daniels, 2015). Injectable progestins have mechanisms of action similar to those for oral progestins and include greater cervical mucus viscosity, creation of an endometrium unfavorable for implantation, and unpredictable ovulation suppression.

Injectable preparations include depot medroxyprogesterone acetate—marketed as *Depo-Provera*. A 150-mg dose is given by intramuscular injection every 90 days. A derivative of DMPA is marketed as *depo-subQ provera 104*, and a 104-mg dose is given subcutaneously every 90 days. Because absorption is slower with subcutaneous injections, the 104-mg dose is equivalent to the 150-mg intramuscular preparation (Jain, 2004). With either method, if the initial dose is given within the first 5 days following menses onset, no back-up contraception is necessary (Haider, 2007). A third injectable depot progestin that is not currently available in the United States is norethindrone enanthate, which is marketed as *Norgest*, and a 200-mg dose is injected intramuscularly every 2 months.

Injectable progestins have contraceptive efficacy equivalent or better than that of COCs. With perfect use, DMPA has a pregnancy rate of 0.2 percent, but typical-use failure rates are as high as 7 percent at 12 months (Trussell, 2018). Depot progesterone does not suppress lactation, and iron-deficiency anemia is less likely in long-term users because of less menstrual bleeding. Progestin injectables should not be taken by women with pregnancy, unexplained uterine bleeding, breast cancer, active or history of thromboembolic disease, cerebrovascular disease, or significant liver disease (Pfizer, 2017).

As with most progestin-only contraceptive methods, DMPA does not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, and blood pressure (Dorflinger, 2002). Moreover, these have not been shown to elevate the risk for VTE, stroke, or cardiovascular disease (Mantha, 2012; World Health Organization, 1998). Despite this, manufacturer prescribing information often lists thrombosis or thromboembolic conditions as contraindications. However, for individuals with these disorders, US MEC considers progestin-containing methods category 2.

Notable Effects. Patients interested in DMPA should be familiar with its potential effects and side effects. First, as is typical of progestin-only contraception, DMPA usually causes irregular menstrual-type bleeding. Cromer and coworkers (1994) reported that one fourth of women discontinued its use in the first year because of irregular bleeding. Amenorrhea may develop after extended use, and women are counseled about this benign effect.

Prolonged ovulation suppression may also persist after DMPA injections are stopped. In an earlier study by Gardner and Mishell (1970), one fourth of women did not resume regular menses for up to a year. Accordingly, DMPA may not be the best choice for women who plan to use contraception only briefly before attempting conception.

Bone mineral density can also be significantly diminished because of lowered estrogen levels and is most worrisome in long-term users. This loss is particularly relevant for adolescents because bone density accrues most rapidly from ages 10 to 30 years (Sulak, 1999). Additionally, decreased bone mineral density may be a concern for perimenopausal women, who will shortly be entering the menopause, a time of known accelerated bone loss. These concerns prompted the FDA in 2004 to require a black-box warning that DMPA "should be used as a long-term birth control method—longer than 2 years—only if other birth-control methods are inadequate." There are some mitigating factors that balance this concern. First, although bone loss is greatest during the first 2 years, it subsequently slows appreciably. Second, most bone lost during contraceptive use is restored within 5 years after its discontinuance (Clark, 2006; Harel, 2010). In sum, the American College of Obstetricians and Gynecologists (2019c) has concluded that concerns of bone density loss should not prevent or limit use of this contraceptive method.

Of potential cancer risks, cervical carcinoma in-situ rates are possibly raised with DMPA use. However, risks for cervical cancer or for hepatic neoplasms are not higher with this method (Thomas, 1995). Advantageously, ovarian and

endometrial cancer rates are *decreased* (Kaunitz, 1996; World Health Organization, 1991). In addition, Skegg and colleagues (1995) pooled the results of the New Zealand and WHO case-control studies that included almost 1800 women with breast cancer. Compared with 14,000 controls, DMPA contraceptive use was associated with a twofold cancer risk in the first 5 years of use. However, the overall risk was not increased.

Of other effects, some women report breast tenderness with DMPA use. Depression also has been noted, but a causal link is unproven. Finally, although weight gain is often attributed to depot progestins, not all studies have shown this (Bahamondes, 2001; Mainwaring, 1995; Moore, 1995; Taneepanichskul, 1998). Beksinska and coworkers (2010) reported that adolescents who used intramuscular DMPA gained 2.3 kg more weight during a 4- to 5-year interval compared with weight gained by adolescents who used COCs. Subcutaneous DMPA also may cause modest weight gain in most women (Westhoff, 2007b). Because women who gain weight in the first 6 months of use are more likely to have long-term progressive weight gain, Le and coworkers (2009) suggest that these women may benefit from early counseling.

THIRD-TIER CONTRACEPTIVE METHODS

Contraceptive methods in this group are considered moderately effective. One type includes barrier methods, which are designed to prevent functional sperm from reaching and fertilizing the ovum. The other category consists of fertility awareness methods. Perhaps more so than with other contraceptive methods, moderately effective methods have the highest success rates when used by couples who are dedicated to their use.

Barrier Methods

These methods include vaginal diaphragms and male and female condoms. As shown in Table 5-1, the reported pregnancy rate for these methods with perfect use varies from 2 to 16 percent in the first year of use and is highly dependent on correct and consistent use.

Male Condom

Most condoms are made from latex rubber, and various sizes are manufactured to accommodate anatomy. Less commonly, polyurethane or lamb cecum is used.

The efficacy of condoms is enhanced appreciably with a reservoir tip. Lubricants should be water based because oil-based products destroy latex condoms and diaphragms (Waldron, 1989). Key steps to ensure maximal condom effectiveness include: (1) used with every coitus, (2) placed before penis and vagina contact, (3) withdrawn while penis still erect, (4) its base held during withdrawal, and (5) used with spermicide.

A distinct advantage of condoms is that, when used properly, they provide considerable—not absolute—protection against many STDs. Condoms also help prevent premalignant cervical changes, probably by blocking HPV transmission (Winer, 2006).

For latex-sensitive individuals, alternative condoms are available. Condoms made from lamb intestines—*natural skin* or *lambskin condoms*—are effective, but they do not provide protection against STDs. Nonallergenic condoms are made with a synthetic thermoplastic elastomer, such as polyurethane, which is also used in some surgical gloves. These are effective against STDs but have significantly higher breakage and slippage rates compared with those of latex condoms (Gallo, 2006). In a randomized trial of 901 couples, Steiner and associates (2003) documented breakage and slippage with 8.4 percent of polyurethane condoms compared with only 3.2 percent of latex condoms. They also reported that 6-month typical pregnancy probabilities were 9.0 percent with polyurethane condoms but only 5.4 percent with latex ones.

Female Condom

Manufactured by many companies under different names, female condoms prevent pregnancy and STDs. One brand available in the United States is the *FC2 Female Condom*—a polyurethane cylindrical sheath with a flexible polyurethane ring at each end (Fig. 5-9). The open ring remains outside the vagina, and the closed internal ring is fitted behind the symphysis and beneath the cervix like a diaphragm (Fig. 5-10). It should not be used with a male condom because together they may slip, tear, or become displaced. In vitro tests show the female condom to be impermeable to HIV, cytomegalovirus, and hepatitis B virus. As shown in Table 5-1, the pregnancy rate is higher than with the male condom.

Diaphragm Plus Spermicide

The diaphragm consists of a circular rubber dome of various diameters supported by a circumferential metal spring (Fig. 5-11). When used in combination with spermicidal jelly or cream, it can be very effective. The spermicide is applied to the cervical surface centrally in the cup and along the rim. The device is then placed in the vagina so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. At the same time, the centrally placed spermicidal agent is held against the cervix by the diaphragm. When appropriately positioned, the rim is lodged deep into the posterior vaginal fornix. Superiorly,

FIGURE 5-9 Female condom. (Reproduced with permission of The Cervical Barrier Advancement Society and Ibis Reproductive Health.)

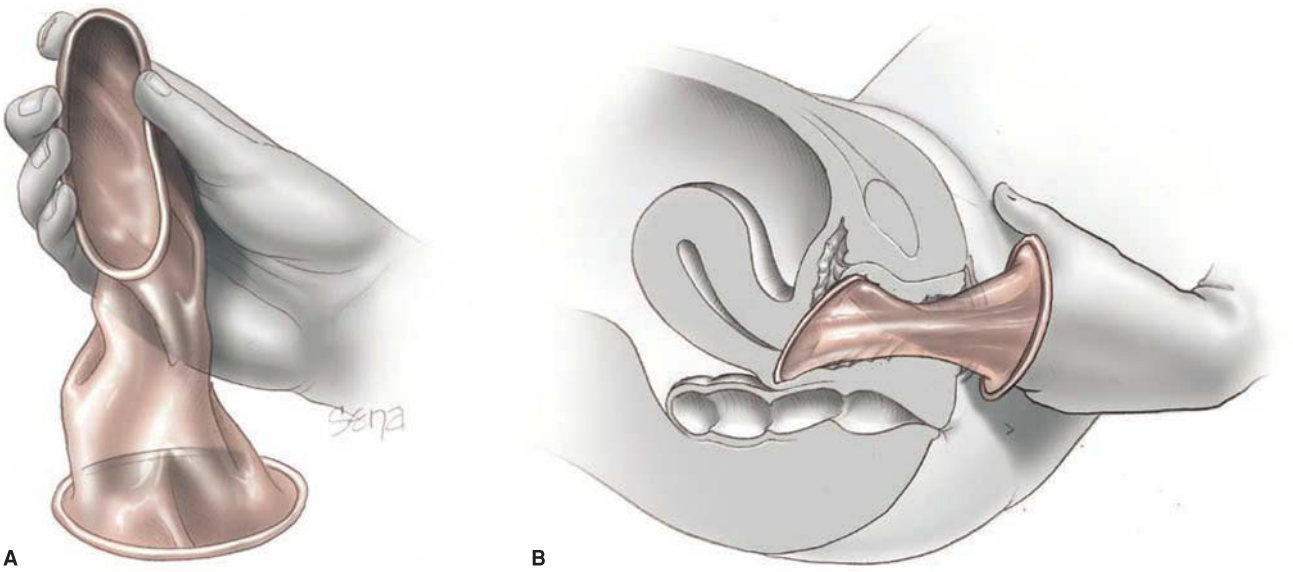

FIGURE 5-10 Female condom insertion and positioning. **A.** The inner ring is squeezed for insertion and is placed similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

the rim lies in close proximity to the inner surface of the symphysis immediately below the urethra (Fig. 5-12). If the diaphragm is too small, it will not remain in place. If too large, it will be uncomfortable when positioned. Because the variables of size and spring flexibility must be specified, the diaphragm is available only by prescription. Because of the requirement for proper placement, the diaphragm may not be an effective choice for women with significant pelvic organ prolapse. The malpositioned uterus can cause unstable diaphragm positioning that results in expulsion.

For use, the diaphragm and spermicidal agent can be inserted well before intercourse, but if more than 2 hours elapse, additional spermicide is placed in the upper vagina for maximum protection. Spermicide is similarly placed before each episode of coitus. The diaphragm is not removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, the diaphragm is not left in place for longer than 24 hours.

Proper diaphragm use requires a high level of motivation. Vessey and coworkers (1982) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for compliant users. In a small study, Bounds and associates (1995) reported a much higher failure rate of 12.3 per 100 woman years. The unintended pregnancy rate is lower in women older than 35 years compared with younger women.

Cervical Cap

This reusable, washable, silicone barrier device surrounds the cervix to block sperm passage and is combined with a spermicide. Marketed in the United States, FemCap is currently

FIGURE 5-11 Group of three diaphragms. (Reproduced with permission from The Cervical Barrier Advancement Society and Ibis Reproductive Health.)

FIGURE 5-12 A diaphragm in place creates a physical barrier between the vagina and cervix.

FIGURE 5-13 CycleBeads. During use, the red bead denotes menses onset, and the small black band is advanced for each day of the menstrual cycle. When the white beads are reached, abstinence is observed until brown beads begin again. (Reproduced with permission from Cycle Technologies.)

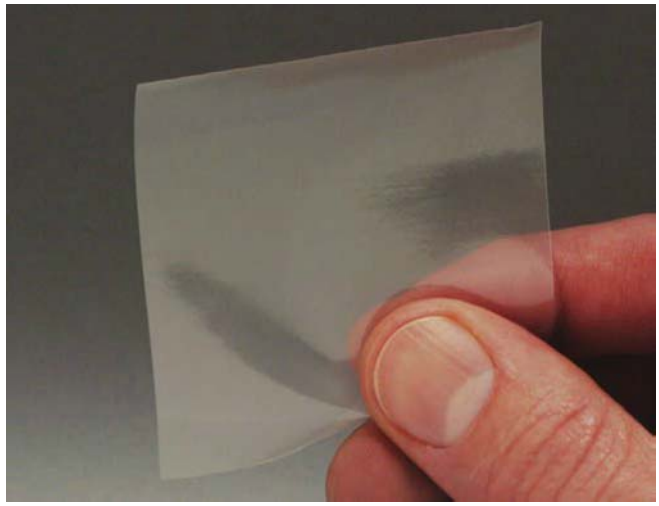

FIGURE 5-14 Vaginal contraceptive film. The film is first folded in half and then folded up and over the tip of the inserting finger. Once inserted near the cervix, the film will dissolve to provide spermicide.

available in 22-, 26-, and 30-mm diameters to accommodate cervical size. It may be inserted any time prior to intercourse and must be left in place for at least 8 hours thereafter. Spermicide dosing and redosing mirrors that with a diaphragm.

Fertility Awareness–Based Methods

This form of contraception involves identification of the fertile days of the menstrual cycle (Fig. 5-13). The couple may then avoid intercourse or use a barrier method during those days. The comparative efficacy of fertility awareness–based methods remains unknown (Peragallo Urrutia, 2018). Clearly, proper instruction is critical, and complex charting is involved. These charts, as well as detailed advice, are available from the FertilityUK for the United Kingdom at: www.fertilityuk.org.

FOURTH-TIER CONTRACEPTIVE METHODS

Spermicides

These contraceptives are marketed variously as creams, jellies, suppositories, aerosol foams, and film (Fig. 5-14). They are used widely in the United States, and most are available without a prescription. Probable users include women who find other methods unacceptable. They are useful especially for women who need temporary protection, for example, during the first week after starting CHC or while nursing.

Spermicidal agents provide a physical barrier to sperm penetration and a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Importantly, spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal effectiveness is usually no more than 1 hour. Thereafter, they must be reinserted before repeat intercourse. Douching, if practiced, is avoided for at least 6 hours after intercourse.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, spermicides are reported to have a failure rate of up to 28 pregnancies per 100 woman-years with perfect use (see Table 5-1). If pregnancy does occur with use, spermicides are not teratogenic (Briggs, 2017).

Spermicides that primarily contain nonoxynol-9 do not provide protection against STDs. Also, long-term use of nonoxynol-9 was reported to have minimal effects on vaginal flora (Schreiber, 2006).

Contraceptive Sponge

The contraceptive sponge *Today* was reintroduced into the United States in 2005. Sold over the counter, it consists of a nonoxynol-9–impregnated polyurethane disc that can be inserted for up to 24 hours prior to intercourse (Fig. 5-15). The

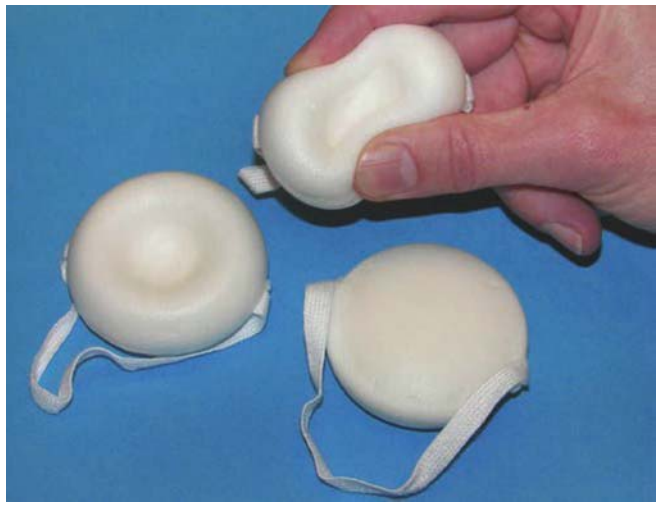

FIGURE 5-15 Vaginal sponge. When in position, the sponge dimple apposes the cervix surface, and the ribbon loop faces outward to allow easy hooking with a finger for removal.

disc is moistened and placed directly against the cervix. While in place, the sponge provides contraception regardless of the number of coital episodes. For efficacy, it remains in place for 6 hours after intercourse, and to lower irritation and infection risks, it remains no longer than 30 hours (Mayer Laboratories, 2011). Although perhaps more convenient, the sponge is less effective than the diaphragm or condom.

EMERGENCY CONTRACEPTION

Emergency contraception (EC) is appropriate for women presenting for contraceptive care following consensual but unprotected sexual intercourse or following sexual assault. If used correctly, several methods will substantially lower the likelihood of an unwanted pregnancy in these women. Methods currently available include sex steroid–containing compounds, antiprogesterone compounds, and the Cu-IUD (Table 5-10). Because duration of use is short, women with conditions that might normally contraindicate hormonal forms may be given these for EC.

Information regarding EC is made available to health care providers or patients by several 24-hour sources:

- American Congress of Obstetricians and Gynecologists: www.acog.org
- Emergency Contraception Hotline and website: 1-888-NOT-2-LATE (888-668-2528) and www.not-2-late.com
- Reproductive Health Technologies Project: rhtp.org/work/contraception/emergency-contraception/.

Hormone-Based Options

Mechanisms of Action

Hormonal contraceptives have different mechanisms of action depending on which day of the menstrual cycle intercourse occurs and which day the tablets are given (Croxatto, 2003). One major mode is inhibition or delay of ovulation (Marions, 2004). Other suggested mechanisms include endometrial changes that prevent implantation, interference with sperm transport or penetration, and impaired corpus luteum function (American College of Obstetricians and Gynecologists, 2018b). Despite these effects, every method used for postcoital contraception will have failures. Pregnancies that develop despite emergency hormonal contraception appear unaffected by this prophylaxis. Moreover, emergency hormonal contraception is not a form of medical abortion. Rather, this method prevents ovulation or implantation.

Except perhaps the copper IUD, other EC methods generally will not prevent pregnancy resulting from subsequent episodes of intercourse during the same cycle. Accordingly, use of a barrier technique is recommended until the next menses. When menstruation is delayed 3 weeks past its expected onset, the likelihood of pregnancy is increased and appropriate testing is instituted.

Estrogen-Progestin Combinations

Also known as the *Yuzpe method*, these COC-containing regimens shown in Table 5-10 have been approved by the FDA for use as EC (Yuzpe, 1974). Pills should be taken within 72 hours

TABLE 5-10. Methods Available for Use as Emergency Contraception

Method	Formulation	Pills per Dose
Progestin-only pill		
Plan B[a]	0.75 mg levonorgestrel	1
Plan B One-Step[b]	150 mg levonorgestrel	1
SPRM pill		
Ella[b]	30 mg ulipristal acetate	1
COC pills[a,c,d]		
Ogestrel	0.05 mg ethinyl estradiol + 0.5 mg norgestrel[e]	2
Lo/Ovral	0.03 mg ethinyl estradiol + 0.3 mg norgestrel[e]	4
Trivora (pink)	0.03 mg ethinyl estradiol + 0.125 mg levonorgestrel	4
Aviane	0.02 mg ethinyl estradiol + 0.1 mg levonorgestrel	5
Copper-containing IUD		
ParaGard T 380A		

[a]Treatment consists of doses taken 12 hours apart.
[b]Treatment consists of a single dose taken once.
[c]Use of an antiemetic agent before taking the medication will lessen the risk of nausea, which is a common side effect.
[d]A listing of other suitable COCs and dosing is found at https://ec.princeton.edu/questions/dose.html#dose.
[e]Norgestrel contains two isomers, and only one of these isomers is bioactive, namely levonorgestrel. Thus, the amount of norgestrel needed for efficacy is twice that of the levonorgestrel-based regimens.
COC = combination oral contraceptive; IUD = intrauterine device; SPRM = selective progesterone-receptor modulator.

of intercourse, are more effective the sooner they are taken, but may be given up to 120 hours. Initial dosing is followed 12 hours later by a second dose.

Efficacy is defined by the number of pregnancies observed after treatment divided by the estimated number that would have occurred with no treatment. This *prevented fraction* ranges widely between reports and averages 75 percent with COC regimens (American College of Obstetricians and Gynecologists, 2018b).

Nausea and vomiting are common with COC regimens because of their high estrogen doses. An oral antiemetic taken at least 1 hour before each dose may reduce symptoms. In randomized trials, a 1-hour pretreatment dose of either 50-mg meclizine or 10-mg metoclopramide was effective (Ragan, 2003; Raymond, 2000). If vomiting occurs within 2 hours of a dose, a replacement dose is given.

Progestin-Only Regimens

A progestin-only method of EC is marketed as *Plan B* and *Plan B One-Step*. Plan B consists of two tablets, each containing 0.75 mg of levonorgestrel. The first dose is taken within 72 hours of unprotected coitus but may be given as late as 120 hours, and the second dose is taken 12 hours later (see Table 5-10). Ngai and associates (2005) also showed that a 24-hour interval between dosing is effective. Plan B One-Step is a single, 1.5-mg levonorgestrel dose, which is taken ideally with 72 hours or up to 120 hours following intercourse.

Most studies, including a multicenter WHO trial, indicate that the progestin-only regimens are more effective than COC regimens to prevent pregnancy (von Hertzen, 2002). The American College of Obstetricians and Gynecologists (2018b) cites an approximately 50-percent lower pregnancy rate with levonorgestrel compared with COCs. Ellertson and colleagues (2003) reported a 55-percent pregnancy prevention rate even if Plan B was taken as late as 4 to 5 days after unprotected intercourse. From small studies, newer pharmacokinetic data suggest lower bioavailability of a 1.5-mg dose in obese women compared with normal-weight patients (Natavio, 2019; Praditpan, 2017). Still, the pregnancy rate in obese women prescribed this EC type was only 2 percent in one pooled analysis (Festin, 2017).

Selective Progestin-Receptor Modulators

In 2010, ulipristal acetate—*Ella*—was FDA approved for postcoital contraception. It is taken as a single 30-mg tablet up to 120 hours after unprotected intercourse (Brache, 2010). This agent, described in Chapter 9 (p. 208), provides contraceptive activity by delaying ovulation. Compared with levonorgestrel in randomized trials, ulipristal acetate proved slightly more effective (Crenin, 2006; Glasier, 2010). Side effects include nausea and delay of subsequent menses.

Copper-Containing Intrauterine Devices

Insertion of a Cu-IUD is an effective postcoital contraceptive method and can be inserted up to 5 days following unprotected intercourse in IUC candidates. It is the most effective method of EC, and one systematic review of 42 studies calculated a pregnancy rate of 0.1 percent (Cleland, 2012). A secondary advantage is that this method also puts in place an effective 10-year method of contraception.

TERMINOLOGY

Abortion is the spontaneous or induced termination of pregnancy before fetal viability. Thus, miscarriage and abortion appropriately are terms used interchangeably in a medical context. But, because popular use of abortion by laypersons implies a deliberate intact pregnancy termination, many prefer miscarriage for spontaneous fetal loss. Both terms will be used throughout this chapter.

For statistical and legal purposes, viability is usually defined by pregnancy duration and fetal birthweight. The Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) define abortion as any pregnancy termination—spontaneous or induced—before 20 weeks' gestation or with a fetus born weighing <500 g. Confusion may be introduced by individual states whose laws define abortion more widely.

Technologic developments have revolutionized current abortion terminology. Transvaginal sonography (TVS) and precise measurement of serum beta human chorionic gonadotropin (β-hCG) concentrations help to identify extremely early pregnancies and to clarify intrauterine versus ectopic location. The term *pregnancy of unknown location (PUL)* aids timely identification and management of ectopic pregnancy. In the context of early pregnancies, five categories have been proposed: definite ectopic pregnancy, probable ectopic, PUL, probable intrauterine pregnancy (IUP), and definite IUP (Barnhart, 2011). Management options for ectopic pregnancies are described in Chapter 7 (p. 168). Of IUPs, those that spontaneously abort during the first trimester, that is, within the first $12^{6/7}$ weeks of gestation, are also defined as *early pregnancy loss* by the American College of Obstetricians and Gynecologists (2018a). *Recurrent pregnancy loss* is variably defined but is meant to identify women with repetitive miscarriage.

If studies are confined to first-trimester abortions, up to 70 percent are *anembryonic*, that is, with no identifiable embryonic elements (Du, 2018; Soler, 2017). The previous term *blighted ovum* is no longer preferred. The remaining pregnancies are *embryonic* miscarriages, which may be further grouped as either those with chromosomal anomalies—*aneuploid abortions*, or those with a normal chromosomal complement—*euploid abortions*.

SPONTANEOUS ABORTION

Incidence

More than 80 percent of spontaneous abortions occur during the first 12 weeks of gestation (American College of Obstetricians and Gynecologists, 2018a). Their rate increases significantly with advancing maternal age. For example, the clinical miscarriage rate nearly doubles with maternal or paternal age older than 40 (Gracia, 2005; Kleinhaus, 2006).

The reported incidence of spontaneous abortion varies with the sensitivity of methods used to identify them. Wilcox and colleagues (1988) studied 221 healthy women through 707 menstrual cycles. They used highly specific assays sensitive to minute concentrations of maternal serum β-hCG and found that 31 percent of pregnancies were lost after implantation. Importantly, two thirds of these very early losses were *clinically silent*.

TABLE 6-1. Chromosomal Findings in Early Abortuses

Chromosomal Studies	Reported Incidence Range (Percent)
Normal (euploid)	
46,XY and 46,XX	45–55
Abnormal (aneuploid)	
Autosomal trisomy	22–32
Monosomy X (45,X)	5–20
Triploidy	6–8
Tetraploidy	2–4
Structural anomaly	2
Double or triple trisomy	0.7–2

Data from Eiben, 1990; Kajii, 1980; Simpson, 1980, 2007.

Fetal Factors

Approximately half of embryonic first-trimester miscarriages are aneuploid. This incidence declines markedly with advancing gestation at the time of pregnancy loss. In general, aneuploid fetuses abort earlier than those with a normal chromosomal complement. Kajii (1980) reported that 75 percent of aneuploid fetuses aborted before 8 weeks, whereas the rate of euploid abortions peaks at approximately 13 weeks. Almost 95 percent of chromosomal abnormalities in aneuploid fetuses are caused by maternal gametogenesis errors (Jacobs, 1980). Importantly, the American College of Obstetricians and Gynecologists (2018a) does not recommend routine use of chromosomal microarray analysis of first-trimester fetal tissues.

Aneuploid Abortion

Trisomy describes the condition in which three copies of a given chromosome are present. Shown in Table 6-1, *autosomal trisomy* is the most frequently identified chromosomal anomaly in early miscarriages. Although most trisomies result from *isolated nondisjunction*, balanced structural chromosomal rearrangements are present in one partner in approximately 2 percent of couples with recurrent pregnancy loss (Barber, 2010).

Monosomy X (45,X) is the single most common specific chromosomal abnormality, also known as *Turner syndrome*. Most affected fetuses spontaneously abort, but some are liveborn females (Chap. 19, p. 412). Conversely, *autosomal monosomy* is rare and incompatible with life.

Ploidy describes the number of complete chromosome sets. *Triploidy* is often associated with hydropic or molar placental degeneration (Chap. 37, p. 777). Of hydatidiform moles, partial moles are characteristically triploid. The associated triploid fetuses frequently abort early, and those born later are all nonviable and grossly malformed. Advanced maternal and paternal ages do not increase the incidence of triploidy. *Tetraploid* fetuses most often abort early in gestation and are rarely liveborn.

Chromosomal structural abnormalities infrequently cause abortion. Neonates with a balanced translocation who are liveborn usually appear normal, but as adults they may experience recurrent pregnancy loss (p. 145).

Euploid Abortion

The causes of euploid abortions are poorly understood, but various maternal medical disorders, uterine defects, and environmental and lifestyle conditions have been implicated. The subsequent etiologies are most logically discussed with sporadic spontaneous abortion. Those most strongly linked to recurrent loss are described later (p. 144).

Maternal Factors

Medical Disorders

Pregnancy loss is clearly associated with diabetes mellitus and thyroid disorders, as discussed on page 149. Inflammatory bowel disease and systemic lupus erythematosus—especially antiphospholipid syndrome—may independently also raise the risk (Khashan, 2012; Ling, 2018; Wu, 2018). Beyond these, few acute or chronic diseases convey early pregnancy risk.

Infection

Only a few organisms are proven to cause abortion. In general, systemic infections likely infect the fetoplacental unit by a blood-borne route. Others may infect locally via maternal genitourinary infection or colonization. Importantly, some infections truly cause miscarriage, whereas others may serve as only an associated marker.

Chlamydia trachomatis is suspected to cause abortion. The mechanism is unclear, but this infection may adversely affect outcome by infecting the fetus, by stimulating a fetal inflammatory response, or by promoting an excessive maternal immunologic reaction (Baud, 2011; Prasad, 2017). An association between *bacterial vaginosis* and first-trimester miscarriage is controversial (Haahr, 2019; Kuon, 2017). Of others, one metaanalysis showed that Ebola virus and *Mycoplasma genitalium* infection were significantly associated with spontaneous abortion (Lis, 2015; Lyman, 2018). Data concerning the abortifacient effects of some other infections are conflicting. Namely, roles for *Mycoplasma hominis* and *Ureaplasma urealyticum* are unclear (Quinn 1983a,b; Temmerman, 1992). Human immunodeficiency virus infection is not associated with excessive abortion risks (Haddad, 2017). Of other viruses, human papilloma virus (HPV) infects trophoblasts, but it does not appear to play a role in miscarriage (Ambühl, 2017). Infections caused by parvovirus, cytomegalovirus, herpes simplex virus, or *Listeria monocytogenes* likely have no abortifacient effects (Brown, 1997; Feldman, 2010; Yan, 2015). Last, several infections cause abortion in livestock, but data remain inconclusive in humans. These include *Brucella abortus*, *Campylobacter fetus*, and *Toxoplasma gondii* (Feldman, 2010; Hide, 2009).

Imaging and Surgery

With low-dose radiation from diagnostic imaging, embryofetal risks appear to be minimal. Current evidence suggests that malformation, growth restriction, or miscarriage rates are not increased from a radiation dose less than 0.05 Gy (5 rad). Indeed, Brent (2009) concluded that gross congenital malformation rates would not be higher with exposure to less than 0.2 Gy (20 rad). Because diagnostic x-rays seldom exceed 0.1 Gy (10 rad),

Strzelczyk and associates (2007) concluded that these procedures are unlikely to cause disordered embryogenesis. With computed tomography, radiation doses can be higher. Thus, modified protocols or substitution with magnetic resonance (MR) imaging is preferred. Importantly, with MR imaging, use of gadolinium is not recommended unless benefits outweigh risks (American College of Radiology, 2018).

For surgery during pregnancy, the risk of miscarriage is not well studied. No currently used anesthetic agents have teratogenic effects when used at any gestational age. *Uncomplicated* surgical procedures—including abdominal or pelvic surgery—do not appear to increase the miscarriage risk (Mazze, 1989). The American College of Obstetricians and Gynecologists (2019c) recommends that elective surgery be postponed until delivery and nonurgent surgery be performed in the second trimester. This practice lowers the theoretical risk for miscarriage or preterm contractions. Laparoscopy also is suitable, and adaptations for pregnancy are described in Chapter 41 (p. 875) (Pearl, 2017).

Ovarian tumors or cysts can be safely resected without causing pregnancy loss. An important exception involves early removal of the corpus luteum or the ovary in which it resides. If performed prior to 10 weeks' gestation, supplemental progesterone is given. Between 8 and 10 weeks, a single 150-mg injection of intramuscular 17-hydroxyprogesterone caproate is given at the time of surgery. If the corpus luteum is excised between 6 to 8 weeks, two additional 150-mg injections are given 1 and 2 weeks after the first. Other suitable progesterone replacement regimens include: (1) micronized vaginal progesterone (Prometrium) 200 mg twice or three times daily; (2) 8-percent progesterone vaginal gel (Crinone) 90 mg once or twice daily; (3) progesterone vaginal insert (Endometrin) 100 mg twice or three times daily; (4) micronized oral progesterone (Prometrium) 200 mg orally twice or three times daily; or (5) progesterone in oil (compounded in a specialty pharmacy) 50 to 100 mg daily intramuscular injection. Any of these regimens is continued until 10 weeks' gestation.

Trauma seldom causes first-trimester miscarriage, and although Parkland Hospital is a busy trauma center, this is an infrequent association. Major trauma—especially abdominal—can cause fetal loss but is more likely as pregnancy advances.

Radiotherapy and Chemotherapy

In utero exposure to radiation may be abortifacient, teratogenic, or carcinogenic depending on the level of exposure and stage of fetal development. Threshold doses that cause abortion are not precisely known but definitely lie within the therapeutic doses used for maternal disease treatment (Williams, 2010). Methotrexate is a known teratogen, and its effects on early pregnancy are described later (p. 153).

Female cancer survivors who were treated in the past with abdominopelvic radiotherapy may be at higher risk for miscarriage. Wo and Viswanathan (2009) reported a two- to eightfold greater risk for miscarriage, perinatal mortality, preterm delivery, and low-birthweight and growth-restricted neonates in women with prior radiotherapy. Hudson (2010) found a higher miscarriage risk in those given radiotherapy and chemotherapy in the past for a childhood cancer.

Medications and Vaccines

Certain medications are known abortifacients and include progesterone antagonists, prostaglandin E_1 (misoprostol), and methotrexate. A complete listing of medications associated with miscarriage lies outside this chapter's scope. The prescribing information document for each drug is best consulted prior to use.

Many routine immunizations can be given safely during pregnancy. Most studies have demonstrated safety of both the HPV and influenza vaccines if given in early pregnancy (Donahue, 2017; McMillan, 2015; Scheller, 2017). However, most live-virus vaccines are proscribed during pregnancy (Table 1-4, p. 11). That said, robust evidence to link live-virus vaccines with miscarriage is lacking.

Nutritional Factors and Weight

Dietary deficiency of any one nutrient or moderate deficiency of all nutrients does not appear to be an important cause of abortion. Even in extreme cases—for example, hyperemesis gravidarum—abortion is rare. Dietary quality may be important, and miscarriage risk is reportedly reduced in women who consume fruit, vegetables, whole grains, and fish (Gaskins, 2015).

Data also suggest that extremes in weight can be deleterious. Obesity is associated with subfertility, raises the risk of miscarriage, and results in a host of other adverse pregnancy outcomes (Boots, 2014). In one study of 6500 women with in vitro fertilization (IVF)-conceived pregnancies, the pregnancy and live birth rates were reduced progressively for each incremental rise in body mass index (BMI) units (Bellver, 2010a). Although the risks for many adverse late-pregnancy outcomes decline after bariatric surgery, its salutary effect on the miscarriage rate is unclear (Guelinckx, 2009).

Low BMI in some but not all studies has been associated with greater miscarriage risk (Balsells, 2016; Metwally, 2010). A cohort of more than 90,000 women demonstrated that the primary modifiable prepregnant risk factors for miscarriage are being underweight, obese, or aged 30 years or older at conception (Feodor Nilsson, 2014).

Behavior

Of lifestyle choices, alcohol use has been best studied in pregnancy. Earlier observations were that both miscarriage and fetal anomaly rates rose with alcohol abuse rates during the first 8 weeks of gestation (Floyd, 1999). Such outcomes likely are dose related, although safe levels have not been identified. Maconochie (2007) observed a significantly greater risk only with regular or heavy alcohol use. In some studies, low-level alcohol consumption apparently did not significantly raise the abortion risk (Avalos, 2014; Feodor Nilsson, 2014). In contrast, Danish National Birth Cohort data suggest an adjusted hazard ratio for first-trimester fetal death of 1.66 with as few as two drinks per week (Andersen, 2012).

In the United States, 7 percent of women who delivered in 2016 were cigarette smokers (Drake, 2018). Cigarettes may cause early pregnancy loss by several mechanisms that also cause adverse late-pregnancy outcomes (Pineles, 2014). Some

but not all studies link smoking with abortion risk and find a dose-response effect (Nielsen, 2006; Westreich, 2017).

"Heavy" caffeine consumption has been associated with greater abortion risk, and this association is enhanced in smokers (Morales–Suárez–Valera, 2018). Studies of "moderate" intake—less than 200 mg daily—do not demonstrate a higher risk (Savitz, 2008; Weng, 2008). Currently, the American College of Obstetricians and Gynecologists (2018d) concludes that moderate consumption likely is not a major abortion risk and that any associated risk with higher intake is unsettled.

The adverse effects of illicit drugs on early pregnancy loss also are unclear. Although cocaine was linked to an increased miscarriage rate in one study, reanalysis refuted this conclusion (Mills, 1999; Ness, 1999).

Occupation and Environment

Some environmental toxins such as benzene are implicated in fetal malformations, but data regarding miscarriage risk are less clear (Lupo, 2011). Earlier reports implicated arsenic, lead, formaldehyde, benzene, and ethylene oxide (Barlow, 1982). More recently, evidence suggests that bisphenol A, polychlorinated biphenyls, and DDT (dichlorodiphenyltrichloroethane) may raise miscarriage rates (Krieg, 2016). Nevertheless, DDT-containing insecticides are endorsed by the WHO (2011) for mosquito control to prevent malaria.

Few studies have assessed occupational exposure and abortion risks. An elevated risk has been described for dental assistants exposed to 3 or more hours of *nitrous oxide* per day in offices without gas-scavenging equipment (Rowland, 1995). In their metaanalysis, Dranitsaris and colleagues (2005) found a small incremental risk for spontaneous abortion in women who worked with cytotoxic antineoplastic chemotherapeutic agents.

Clinical Classification

As a group, abortion can be divided clinically several ways. Commonly used categories include threatened, inevitable, incomplete, complete, and missed abortion. When the products of conception and uterus become infected, the term *septic abortion* is used.

Threatened Abortion

The diagnosis of *threatened abortion* is presumed when bloody vaginal discharge or blood exits through a closed internal cervical os during the first 20 weeks of gestation. In early pregnancy, bleeding is common and includes that with blastocyst implantation at the time of expected menses. Approximately one fourth of pregnant women experiences first-trimester spotting or bleeding. Of these, 43 percent will subsequently miscarry. Bleeding is by far the most predictive risk factor for pregnancy loss, but this risk is substantially less if fetal cardiac activity is seen sonographically (Tongsong, 1995). However, the combination of bleeding and uterine cramping predicts a poor prognosis for pregnancy continuation. Even if miscarriage does not follow early bleeding, the risks for later adverse pregnancy outcomes are elevated (Table 6-2). In a study of almost 1.8 million pregnancies, the risk for many of these pregnancy complications rose threefold (Lykke, 2010).

TABLE 6-2. Increased Incidence of Some Adverse Outcomes in Women with Threatened Abortion

Maternal	Perinatal
Placenta previa	Preterm ruptured membranes
Placental abruption	Preterm birth
Manual removal of placenta	Low-birthweight infant
Cesarean delivery	Fetal-growth restriction
	Perinatal death

From Johns, 2006; Lykke, 2010; Saraswat, 2010; Wijesiriwardana, 2006.

Diagnosis. In a woman with an early pregnancy, vaginal bleeding will prompt evaluation. The primary goal is to diagnose abnormal pregnancies that include spontaneous abortion, ectopic pregnancy, or molar pregnancy. With initial physical evaluation, abdominal tenderness and its location are sought. During speculum examination, blood flow from the cervix is assessed, and a swab or ring forceps gently probes for internal cervical os integrity. The external os is less informative and is often slightly dilated in parous women. Of laboratory tests, hematocrit, blood type, and a quantitative serum β-hCG level are determined. Last, TVS can help ascertain if the fetus is alive and if it is within the uterus. Repeat evaluations are often necessary as neither β-hCG nor TVS has 100-percent accuracy for the diagnosis of pregnancy location or fetal viability. Several predictive models based on serum β-hCG levels done 48 hours apart have been described (Barnhart, 2010; Condous, 2007). Of these, serum β-hCG levels with a robust uterine pregnancy should increase at least 33 to 49 percent every 48 hours depending on the baseline level (American College of Obstetricians and Gynecologists, 2018f). In contrast, Table 7-2 (p. 165) depicts serum β-hCG level disappearance in women with a PUL and bleeding who ultimately went on to have an early miscarriage.

A serum progesterone level can be added to provide information, although its sensitivity is poor. Levels <5 ng/mL suggest a dying pregnancy. Values >20 ng/mL support the diagnosis of a healthy pregnancy. However, progesterone levels often lie between these thresholds, are then considered indeterminate, and thus are less informative.

TVS can document the location and viability of a gestation. If this cannot be done, then a PUL is diagnosed. Notably, a consensus conference in 2012 concluded that prior sonographic criteria for fetal viability yielded unacceptably high rates of viable IUPs being falsely diagnosed as nonviable or as PULs (American College of Obstetricians and Gynecologists, 2018a; Doubilet, 2014). Such errors can lead to unnecessary surgical or medical treatment, interruption of a viable IUP, or incorrect assumption that a woman is at recurrent risk for an ectopic pregnancy. Because of this, as shown in Table 6-3, more stringent guidelines were proposed to diagnose pregnancy failure (Doubilet, 2014).

TABLE 6-3. Society of Radiologists in Ultrasound Guidelines for Early Pregnancy Loss Diagnosis

Diagnostic Sonographic Findings
CRL ≥7 mm and no heartbeat
MSD ≥25 mm and no embryo
Absence of embryo with heartbeat ≥2 weeks after a scan showed a gestational sac without a yolk sac
Absence of embryo with heartbeat ≥11 days after a scan showed a gestational sac with a yolk sac

CRL = crown-rump length; MSD = mean sac diameter.

One early TVS sign of an IUP is the gestational sac. This anechoic fluid collection represents the exocoelomic cavity. It may be encircled by two echogenic external layers, the *double-decidual sign*, which represent the decidua parietalis and decidua capsularis (Fig. 6-1). The gestational sac can usually be seen by 4.5 weeks with maternal β-hCG levels between 1500 and 2000 mIU/mL (Barnhart, 1994). More recently, Connolly and colleagues (2013) reported that a threshold value of 3500 mIU/mL may be required to detect a gestational sac in 99 percent of cases. This level is now recommended by the American College of Obstetricians and Gynecologists (2018f). Importantly, a gestational sac may appear similar to other intrauterine fluid accumulations such as the *pseudogestational sac (pseudosac)* present with ectopic pregnancy (Fig. 7-4, p. 165). A pseudosac may be excluded once a definite yolk sac or embryo is seen inside the sac. The diagnosis of an IUP should be made cautiously if the yolk sac is not yet seen (American College of Obstetricians and Gynecologists, 2018g).

The yolk sac is a circular, 3- to 5-mm-diameter anechoic structure. It is typically seen within the gestational sac at approximately 5.5 weeks' gestation and with a mean sac diameter (MSD) ≥10 mm. At approximately 6 weeks' gestation, a 1- to 2-mm embryo adjacent to the yolk sac can be found (see Fig. 6-1). Absence of an embryo in a sac with a MSD of 16 to 24 mm is suspicious for pregnancy failure (Doubilet, 2014). Cardiac motion can be detected at 6 to 6.5 weeks' gestation, at an embryonic length of 1 to 5 mm. Shown in Table 6-3, absent cardiac activity at certain stages can be used to diagnose pregnancy failure.

Management. With threatened abortion, bed rest is often recommended but does not improve outcomes. Neither has treatment with a host of medications and hormones that include progesterone and chorionic gonadotropin (Devaseelan, 2010). Acetaminophen-based analgesia will help relieve cramping discomfort. If anemia or hypovolemia is significant from active bleeding, pregnancy evacuation is generally indicated. In cases in which there is a live fetus, less often, some instead may choose transfusion and further observation.

Inevitable Abortion

Amnionic fluid leaking through a dilated cervix portends almost certain abortion. Sonography will usually show markedly diminished fluid volume. Following such membrane rupture,

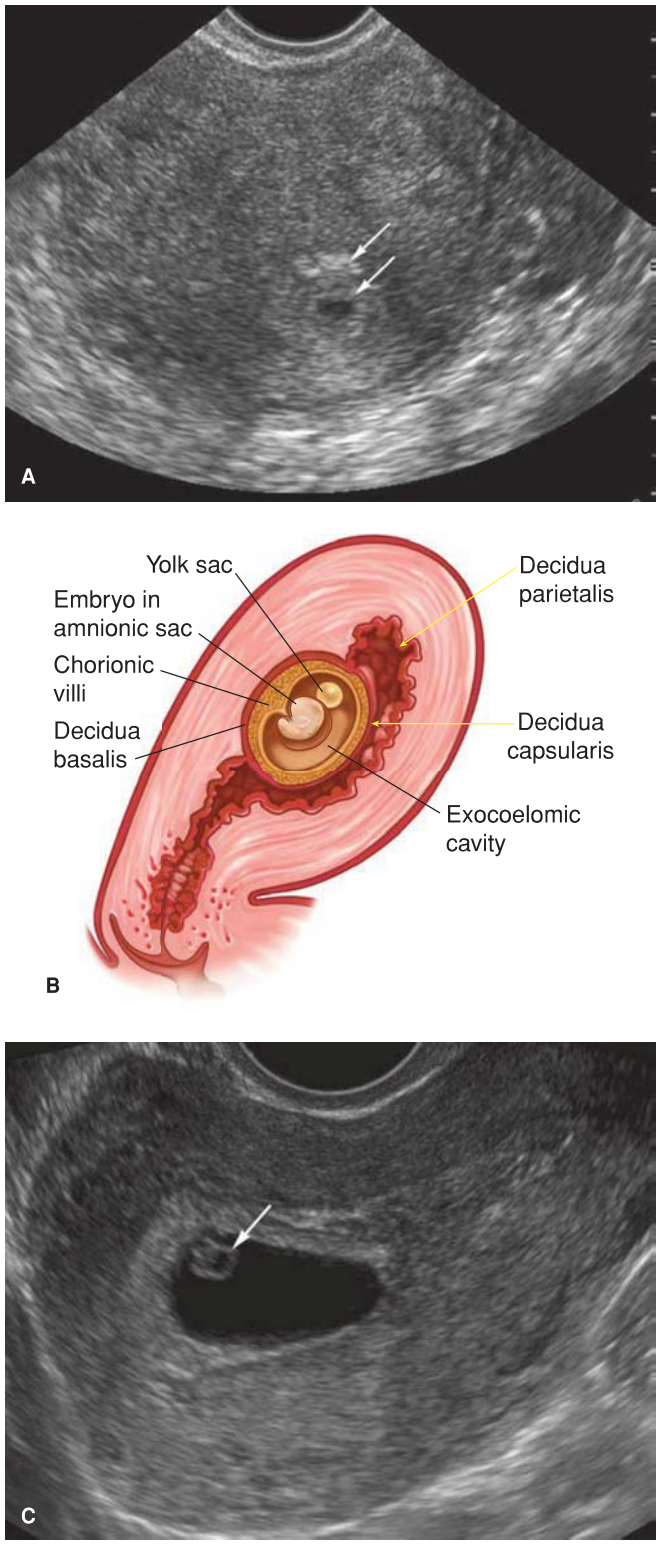

FIGURE 6-1 Early intrauterine pregnancy. **A.** Sonogram shows the anechoic gestational sac surrounded by two concentric echogenic layers, which are the inner decidua capsularis (*arrow*) and the peripheral decidua parietalis (*arrow*). **B.** The drawing shows the anatomy of an early pregnancy. **C.** The yolk sac (*arrow*) is circular and anechoic, and in this image, it lies to the right of its adjacent embryo.

TABLE 6-4. Randomized Controlled Studies for Management of Early Pregnancy Loss

Study	Inclusion Criteria	No.	Treatment Arms	Outcomes
Nguyen (2005)	Incomplete SAB	149	(1) PGE_1, 600 µg orally (2) PGE_1, 600 µg orally initially and at 4 hour	60% completed at 3 d 95% at 7 d; 3% curettage
Zhang (2005)	Pregnancy failure[a]	652	(1) PGE_1, 800 µg vaginally (2) Vacuum aspiration	71% completed at 3 d; 16% failure 97% successful
Trinder (2006) (MIST Trial)	Incomplete SAB; missed AB	1200	(1) Expectant (2) PGE_1, 800 µg vaginally ± 200 mg mifepristone (3) Suction curettage	50% curettage 38% curettage 5% repeat curettage
Dao (2007)	Incomplete SAB	447	(1) PGE_1, 600 µg orally (2) Vacuum aspiration	95% completed 100% completed
Torre (2012)	First-trimester miscarriage[b]	174	(1) Immediate—PGE_1, 200 µg orally Day 2—400 µg vaginally (2) Delayed—no treatment; TVS days 7 and 14	81% completed 19% curettage 57% completed 43% curettage

[a]Includes anembryonic gestation, embryonic or fetal death, without signs of incomplete SAB.
[b]Includes anembryonic gestation, embryonic or fetal death, or incomplete or inevitable SAB.
SAB = spontaneous abortion; PGE_1 = prostaglandin E_1; TVS = transvaginal sonography.

either uterine contractions begin promptly or infection develops. Rarely is a gush of vaginal fluid during the first half of pregnancy without serious consequence.

In the rare case, fluid may have collected previously between the amnion and chorion and may not be associated with pain, fever, or bleeding. TVS will typically show normal fluid volume. If a live fetus and normal fluid volume is documented, diminished activity with observation is reasonable. After 48 hours, if no additional amnionic fluid has escaped and no bleeding, cramping, or fever is noted, a woman may resume ambulation. Initial abstinence from intercourse and exercise also is recommended. Instead, with bleeding, cramping, or fever, abortion is considered inevitable, and the uterus is evacuated.

Incomplete Abortion

With first-trimester losses, death of the embryo or fetus nearly always precedes spontaneous expulsion. Death of the conceptus is usually accompanied by hemorrhage into the decidua basalis. This is followed by adjacent tissue necrosis that stimulates uterine contractions and expulsion. An intact gestational sac is generally filled with fluid and may or may not contain an embryo or fetus. With miscarriage, bleeding usually begins first, and abdominal cramping follows hours to days later. Low-midline rhythmic cramps; persistent low backache with pelvic pressure; or dull and midline suprapubic discomfort are common symptoms.

Partial or complete placental separation and dilation of the cervical os is termed *incomplete abortion*. The fetus and the placenta may remain entirely within the uterus or partially extrude through the dilated os. Before 10 weeks, they are frequently expelled together, but later in pregnancy, they deliver separately. Management options of incomplete abortion include curettage, medical abortion, or expectant management in clinically stable women (Table 6-4) (Kim, 2017). With surgical therapy, additional cervical dilation may be necessary before suction curettage is performed (p. 152). In others, retained placental tissue simply lies loosely within the cervical canal and allows easy extraction with ring forceps. The removed products of conception are sent to pathology for standard histologic analysis. By this, products of conception are confirmed, and gestational trophoblastic disease is excluded.

Complete Abortion

In some cases, expulsion of the entire pregnancy is completed before a patient presents for care. In such cases, a history of heavy bleeding, cramping, and tissue passage at home is common. On pelvic examination, the cervical os is closed. Patients are encouraged to bring in passed tissue, which may be a complete gestation, blood clots, or a decidual cast. The last is a layer of endometrium in the shape of the uterine cavity that when sloughed can appear as a collapsed sac (Fig. 7-7, p. 167).

If a gestational sac is not identified grossly in the expelled specimen, sonography is performed to differentiate a complete abortion from threatened abortion or ectopic pregnancy. With TVS, characteristic intrauterine findings of a complete abortion include a thickened endometrium without a gestational sac. However, this does not guarantee a recent IUP. Condous and associates (2005) described 152 women with heavy bleeding, an empty uterus with endometrial thickness <15 mm, and a diagnosis of completed miscarriage. Of these, 6 percent were subsequently found to have an ectopic pregnancy. Thus, a diagnosis of complete abortion should not be made unless an intrauterine pregnancy was previously diagnosed sonographically or passage of a gestational sac has been confirmed.

In unclear settings, serial serum β-hCG measurements aid clarification. With complete abortion, these levels drop quickly. Pocius and coworkers (2017) found a mean serum decline of 70 percent after 2 days and a minimum decline of 36 percent. After 4 days, these values were 91 percent and 64 percent, respectively.

Missed Abortion—Early Pregnancy Loss

The term *missed abortion* requires clarification. Historically, the term was used to describe dead products of conception that were retained for weeks or months in a uterus with a closed cervical os. Despite this, concurrent early pregnancy findings of amenorrhea, nausea and vomiting, breast changes, and uterine growth appeared normal. To elucidate these disparities, Streeter (1930) studied aborted fetuses and observed that the mean interval from death to abortion was approximately 6 weeks.

This historical description of missed abortion is in contrast to that defined currently based on results of serial serum β-hCG assays and TVS (Fig. 6-2 and Table 6-3). With these tools, fetal or embryonic death is confirmed relatively rapidly—even in early pregnancies. Although many classify this as a missed abortion, the term is used interchangeably with *early pregnancy loss* (Silver, 2011). Management options include dilation and curettage, medical abortion, or expectant management (see Table 6-4).

Septic Abortion

Horrific infections and maternal deaths associated with septic abortions have become rare with legalized abortion. With current abortion practices, rates are <1 percent (Achilles, 2011; Upadhyay, 2015). That said, elective abortion, either surgical or medical, is occasionally complicated by severe and even fatal infections. Bacteria gain uterine entry and colonize dead conception products. Organisms may invade myometrial tissues and extend to cause parametritis, peritonitis, septicemia, and rarely, endocarditis (Vartian, 1991).

FIGURE 6-2 Transvaginal sonogram in the sagittal plane showing a gravid uterus. Calipers mark the sac borders of this anembryonic gestation.

Infections are usually polymicrobial. But, significant necrotizing infections and toxic shock syndrome can be caused by group A streptococcus—*S pyogenes* (Daif, 2009). In addition, rare but severe infections with otherwise low-virulence organisms have complicated medical abortions. These include deaths from toxic shock syndrome due to *Clostridium perfringens* (Centers for Disease Control and Prevention, 2005). Similar infections caused by *Clostridium sordellii* and *novyi* have clinical manifestations that begin within a few days after an abortion. Women may be afebrile when first seen with prominent endothelial injury, capillary leakage, hemoconcentration, hypotension, and a profound leukocytosis (Fischer, 2005; Herrera, 2016; Ho, 2009). Maternal deaths from these clostridial species approximate 0.58 per 100,000 medical abortions (Meites, 2010).

Treatment of infected abortion or postabortal sepsis includes prompt administration of broad-spectrum antibiotics. Suitable regimens are found in Table 3-16 (p. 82). For women with septic incomplete abortion or for those with retained fragments, intravenous antimicrobial therapy is promptly followed by uterine evacuation. Most women respond to this treatment within 1 to 2 days and are discharged when afebrile. Continued outpatient oral antibiotic treatment is likely unnecessary (Savaris, 2011). Rarely, sepsis causes acute respiratory distress syndrome, acute kidney injury, or disseminated intravascular coagulopathy. In these cases, intensive supportive care is essential.

To prevent postabortal sepsis, prophylactic antibiotics are given at the time of surgical evacuation of incomplete or induced abortion. Guidelines recommend doxycycline as a sole 200-mg oral preoperative dose (American College of Obstetricians and Gynecologists (2018a,e).

Management

Unless there is serious bleeding or infection, management of spontaneous abortion can be individualized. Any of three management options is reasonable—expectant, medical, or surgical (see Table 6-4). Each has its own risks and benefits. For example, the first two are associated with unpredictable bleeding, and some women will require unscheduled curettage. Nevertheless, expectant management for suspected first-trimester miscarriage results in spontaneous resolution of pregnancy in more than 80 percent of women (Luise, 2002). Whereas surgical treatment is definitive and predictable, it is invasive and not necessary for all women. If anemia or hypovolemia is significant, pregnancy evacuation is generally indicated.

Several randomized studies that compared these management schemes have been reviewed (Kim, 2017; Neilson, 2013; Wu, 2017). A major drawback cited for between-study comparisons was varied inclusion criteria and techniques. For example, studies that included women with vaginal bleeding enhanced the success of medical therapy compared with studies that excluded such women (Creinin, 2006).

The selected studies in Table 6-4 permit some generalizations. First, success is dependent on the type of early pregnancy loss, that is, incomplete versus missed abortion. Second, expectant management of spontaneous incomplete abortion has failure rates as high as 50 percent. Curettage results in a quick

resolution that is 95- to 100-percent successful. Last, medical therapy failure rates with prostaglandin E_1 (PGE_1) may be related to dose, route, and form—tablet, gel, dissolved—and rates vary from 5 to 40 percent. The addition of mifepristone and laminaria appear to improve efficacy of PGE_1 (Dunford, 2018; Khooshideh, 2017; Schreiber, 2018). Importantly, subsequent pregnancy rates do not differ among these management methods (Smith, 2009).

As a single agent for medical management, a common standard is misoprostol, given 800 µg vaginally as a single dose (American College of Obstetricians and Gynecologists, 2016b). The dose may be repeated in 1 to 2 days. If mifepristone is selected for pretreatment to misoprostol, an oral dose of 200 mg is given prior to the misoprostol 800-µg vaginal dose (Schreiber, 2018).

During spontaneous miscarriage, 2 percent of D-negative women will become isoimmunized if not provided passive isoimmunization. With an induced abortion, this rate may reach 5 percent. The American College of Obstetricians and Gynecologists (2017a) recommends anti-Rh_0(D)immunoglobulin given as 300 µg intramuscularly (IM) for all gestational ages. Alternatively, some give 50 µg IM for pregnancies ≤12 weeks and 300 µg for ≥13 weeks.

With a threatened abortion, immunoglobulin prophylaxis is controversial, and recommendations are limited by scarce evidence-based data (Hannafin, 2006; Weiss, 2002). Up to 12 weeks' gestation, prophylaxis is optional for women with threatened abortion and a live fetus. At Parkland Hospital, we administer a 50-µg dose to all D-negative women with first-trimester bleeding.

RECURRENT MISCARRIAGE

Terms used to describe repetitive early spontaneous pregnancy losses include *recurrent miscarriage, recurrent spontaneous abortion,* and *recurrent pregnancy loss (RPL)* with the last term gaining popularity. The term *habitual abortion* was used in the past and currently is not preferred. Approximately 1 to 2 percent of fertile couples experience RPL. Most women with recurrent miscarriage have embryonic or early fetal loss. Recurrent anembryonic miscarriage or those with consecutive losses after 14 weeks are much less common.

The definition of RPL varies across professional societies, and revisions stem from new information regarding etiology. It was previously defined as three or more consecutive losses. Now, the American Society for Reproductive Medicine (ASRM) (2012, 2013) and the European Society of Human Reproduction and Embryology (2017) define RPL as the loss of two or more pregnancies (Khalife, 2019; Youssef, 2019). ASRM requires pregnancies to be confirmed by β-hCG levels and either sonographic or histopathologic findings. Losses need not be consecutive. Moreover, the classic definition of pregnancy loss at gestational age <20 weeks or with a fetal weight <500 g is less strictly adhered to. These changes are supported by a study of more than 1000 women in which those with two pregnancy losses had a prevalence of abnormal test findings similar to that of women with three or more losses (Jaslow, 2010). Other evaluation considerations include maternal age and the interval between pregnancies. Evaluation and treatment are considered earlier in couples with concordant subfertility.

TABLE 6-5. Predicted Success Rate of Subsequent Pregnancy According to Age and Number of Previous Miscarriages

Age (years)	No. of Previous Miscarriages: 2	3	4	5
	Predicted Success of Subsequent Pregnancy (%)			
20	92	90	88	85
25	89	86	82	79
30	84	80	76	71
35	77	73	68	62
40+	69	64	58	52

Shown in Table 6-5, the success rate of a subsequent viable pregnancy declines as age increases and as the number of consecutive losses rises. Remarkably, the chances for a successful pregnancy are >50 percent even after five losses in women aged <45 years (Brigham, 1999). Following more than 150,000 miscarriages, Bhattacharya and coworkers (2010) reported miscarriage rate as it related to the number of prior losses (Table 6-6). In both studies, the risk for subsequent miscarriage was similar following either two or three losses.

Etiology

Of the many putative causes of early RPL, only three are widely accepted: parental chromosomal abnormalities, antiphospholipid antibody syndrome, and acquired or congenital uterine abnormalities. Other suspected but not proven causes are alloimmunity, endocrinopathies, and environmental toxins. Discussed earlier, very few infections are firmly associated with early pregnancy loss (p. 138). It is even less likely that infections would cause recurrent miscarriage because most are isolated events or stimulate protective maternal antibodies.

The timing of the recurrent losses may provide a clue to their etiology. For a given individual with RPL, each miscarriage tends to occur near the same gestational age (Heuser, 2010). Genetic factors most frequently result in early embryonic losses, whereas autoimmune or anatomic abnormalities more likely

TABLE 6-6. Predicted Miscarriage Rate with Subsequent Pregnancy Based on Number of Prior Miscarriages[a]

	Previous Pregnancy Losses: 0	1	2	3
Pregnancies (n)	143,595	6577	700	115
Subsequent risk for miscarriage	7.0%	13.9%	26.1%	27.8%

[a]Nonconsecutive miscarriages showed the same pattern of risk as consecutive miscarriages.

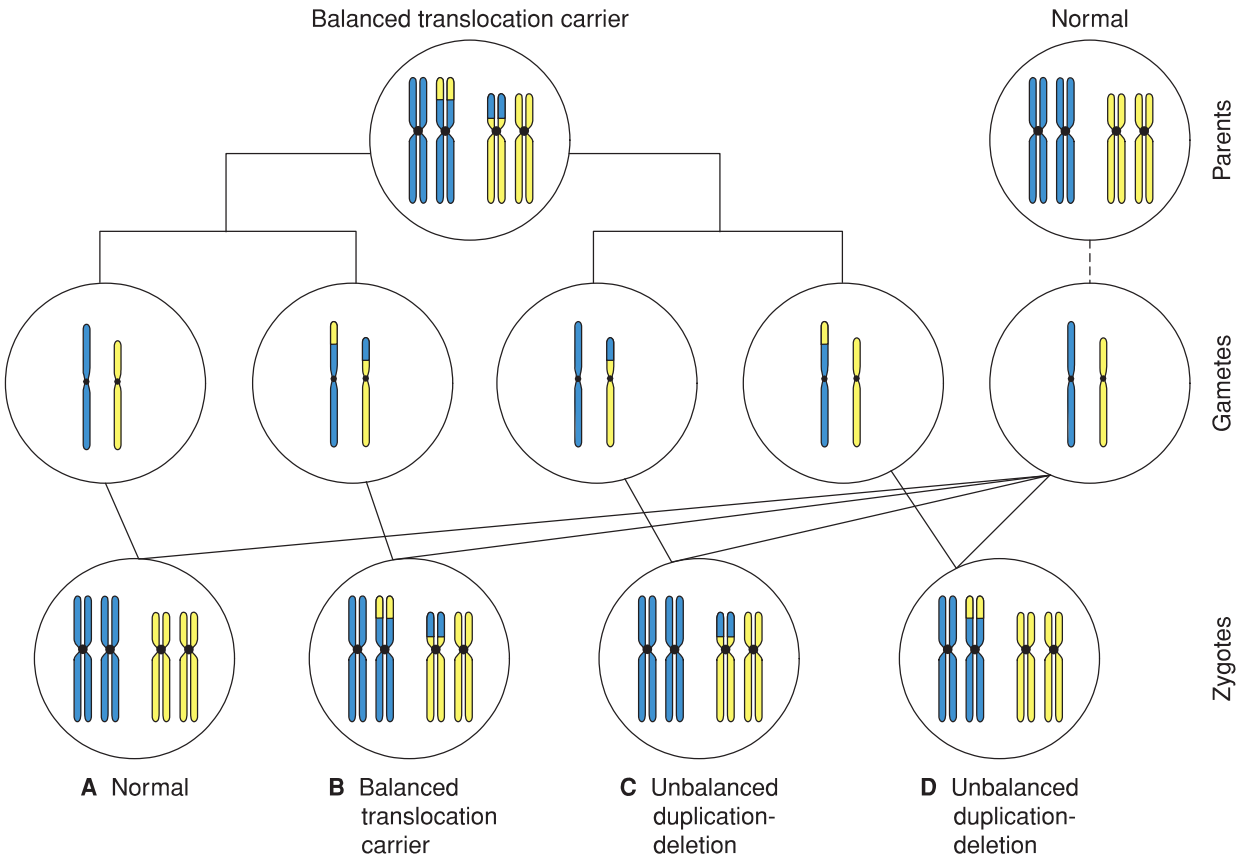

FIGURE 6-3 Gametes produced by a balanced translocation carrier. (Reproduced with permission from Dashe, 2018.)

lead to second-trimester losses. Although many causes of RPL parallel those of sporadic miscarriage, the relative incidence differs between the two categories. For example, recurrent first-trimester losses have a significantly lower incidence of genetic abnormalities than observed in sporadic losses. In one series, the products of conception had a normal karyotype in half of recurrent miscarriages but in only a fourth of sporadic losses (Sullivan, 2004).

Parental Chromosomal Abnormalities

Parental Karyotype

An abnormal parental karyotype is estimated to account for 2 to 5 percent of RPL cases, and karyotype evaluation of both parents is recommended by the American Society for Reproductive Medicine (2012). Data from 8000 couples with two or more miscarriages demonstrated structural chromosomal anomalies in 3 percent—a fivefold greater incidence than observed for the general population. In the parents, balanced reciprocal translocations accounted for 50 percent of identified abnormalities; robertsonian translocations for 24 percent; and X chromosome mosaicism such as 47,XXY—*Klinefelter syndrome*—for 12 percent. Inversions and various other anomalies made up the remainder. The women were twice as likely as the men to harbor the cytogenetic abnormality (Tharapel, 1985). The likelihood of a karyotypic abnormality does not differ between consecutive or nonconsecutive pregnancy losses (van den Boogaard, 2010).

As noted, balanced translocations are the most common structural chromosomal abnormality and result in several possible genetic outcomes in the conceptus: normal, the same balanced translocation, or an unbalanced translocation (Fig. 6-3). Offspring who inherit the balanced translocation also are likely to experience recurrent miscarriage. With an unbalanced translocation, the conceptus will either spontaneously abort or produce an anomalous, frequently stillborn fetus. Thus, a history of second-trimester loss or fetal anomaly raises suspicion that one parent may have an abnormal chromosome pattern.

Sperm DNA Testing

The male genetic contribution to recurrent pregnancy loss has gained greater attention. In couples with RPL, some but not all studies report higher rates of aneuploidy and DNA fragmentation in sperm from a male partner (Bellver, 2010b; Ramasamy, 2015; Robinson, 2012). Additional areas of study include Y chromosome microdeletion, structural chromosomal abnormalities, and shortened telomere length (Ibrahim, 2018).

Although unlikely to be as critical as maternal age, increasing paternal age was significantly associated with a higher abortion risk in one study of more than 92,000 births (Kleinhaus, 2006). This risk was lowest before age 25 years, after which it progressively rose at 5-year intervals. A detrimental effect of paternal age on pregnancy outcomes following intrauterine insemination and IVF also is reported (Belloc, 2008; Robertshaw, 2014). At this time, semen analysis and assays for DNA integrity or other genetic abnormalities are not

recommended as part of RPL evaluation (American Society for Reproductive Medicine, 2012).

Screening Products of Conception

Some recommend that fetal tissue be routinely analyzed for chromosomal abnormalities following a second consecutive miscarriage (Stephenson, 2006). One reason cited is that an abnormal karyotype suggests a sporadic loss and therefore does not predict a greater risk for loss with a subsequent pregnancy. Conversely, an abortus with a normal karyotype might suggest an alternative cause and imply a need for earlier evaluation.

Opponents of such routine karyotyping cite its high cost and possibility of misleading results. This applies particularly if the abnormal cells are derived from a pregnancy with placental mosaicism. Moreover, detection of a 46,XX karyotype may simply reflect contamination with maternal tissues. In sum, karyotyping of products of conception may not accurately reflect fetal karyotype. Because of the expense and limited information provided, we do not recommend this as a routine part of the evaluation at present.

Some are promoting the use of even more complex and expensive genetic techniques. Testing options include comparative genomic hybridization, chromosomal microarray, and copy number sequence technologies. These approaches can detect chromosomal changes below the threshold of sensitivity for conventional cytogenetic analysis (Gao, 2012; Lui, 2015). Some current practicality concerns are being mitigated by the advent of highly accurate 24-chromosome microarray technology and decreasing expense (Popescu, 2018). Thus, future recommendations may change.

Currently, we recommend that RPL evaluation should include a standard karyotype of both parents. More detailed chromosomal evaluation should remain investigational.

Whole Genome Sequencing

Specific genes responsible for human disorders now can be identified through DNA sequencing of the whole genome (whole genome sequencing) or the coding part of the genome (exome). Originally cost prohibitive, associated expense is now at levels in line with routine clinical practice. Thus, this approach has been used successfully in several specialties, but less so in the reproductive field. One hurdle is the ability to distinguish benign from causative variants in the DNA nucleotide sequence. Despite this, important information is expected from this work in the near future (Rajcan-Separovic, 2019).

Treatment

Individualized treatment is indicated in couples with a structural genetic abnormality. Approaches include IVF with preimplantation genetic testing (PGT) or the use of donor gametes. These techniques are described in Chapter 21 (p. 466). Depending on the timing of prior losses, chorionic villus sampling or amniocentesis also may be considered. In one retrospective study of couples with known translocations, PGT was found to increase the successful pregnancy rate and decrease the length of time to conception (Fischer, 2010). Even so, the prognosis is generally good without intervention for couples with a balanced translocation. Franssen and colleagues (2006) compared couples with a balanced translocation and noncarrier couples. In both groups, 85 percent of couples had a healthy child, although the miscarriage rate was higher for the carrier couples.

Some have recommended PGT even in couples with normal karyotypes who have idiopathic RPL (Vitez, 2019). However, results from a large prospective cohort trial found no support for this practice (Platteau, 2005). Currently, the American Society for Reproductive Medicine (2012) does not recommend PGT in couples who are chromosomally normal.

Anatomic Factors

Several uterine abnormalities have been implicated in RPL and other adverse pregnancy outcomes but not in infertility (Reichman, 2010). According to Devi Wold and associates (2006), 15 percent of women with three or more consecutive miscarriages will be found to have an acquired or congenital uterine anomaly. The likelihood of identifying an abnormality is similar whether a patient has experienced two, three, or four consecutive miscarriages. This suggests that cavity evaluation after two miscarriages is reasonable (Seckin, 2012).

Acquired Uterine Defects

Acquired uterine abnormalities associated with pregnancy loss include intrauterine synechiae, leiomyoma, and endometrial polyps. Of these, intrauterine synechiae—also known as *intrauterine adhesions* or as *Asherman syndrome*—usually result from destruction of large areas of endometrium by curettage or ablative procedures. Characteristic multiple filling defects are seen during hysterosalpingography (HSG) or saline-infusion sonography (Fig. 2-23, p. 41 and Fig. 20-6, p. 439). As treatment, directed hysteroscopic lysis of adhesions is preferable to curettage, as discussed and illustrated in Section 44-18 (p. 1069). In one study, adhesiolysis lowered the miscarriage rate from 79 to 22 percent and raised the successful term pregnancy rate from 18 to 69 percent (Katz, 1996). Other studies report similar outcomes with prognosis correlating with disease severity (Al-Inany, 2001; Goldenberg, 1995).

Uterine leiomyomas are found in a large proportion of adult women and can cause miscarriage, especially if located near the placental implantation site. Common sense suggests that detrimental effects should be greater for submucous compared with intramural leiomyomas, and for large versus small tumors. However, uterine cavity distortion is apparently not requisite for bad outcomes, although conclusive data are lacking (Saravelos, 2011). In support, in women undergoing IVF, pregnancy outcomes were adversely affected by submucous but not subserosal or intramural leiomyomas (Jun, 2001; Ramzy, 1998). In contrast, a metaanalysis reported higher rates of adverse pregnancy outcomes—including miscarriage—following IVF in women with intramural myomas (Sunkara, 2010).

Currently, although based on poor-quality data, most agree that consideration be given to excision of submucosal and intracavitary leiomyomas in women with recurrent miscarriage (American Society for Reproductive Medicine, 2017). Uterine artery embolization to treat myomas may increase the risk for subsequent miscarriage and may not be advisable (Homer,

2010). For endometrial polyps, hysteroscopic removal is generally recommended. However, data are limited, particularly for single or small polyps. In all these cases, reproductive benefits are weighed against surgical risks, which include de novo synechiae formation.

Cervical insufficiency, also known as *incompetent cervix*, may develop following surgical or birth trauma. It may also be associated with a molecular defect in collagen synthesis (Dukhovny, 2009). Cervical insufficiency does not cause first-trimester miscarriage but is associated with a greater risk for second-trimester loss. The classic presentation is painless cervical dilation after 16 to 18 weeks' gestation. Cervical insufficiency is often treated surgically with cerclage placement. Interested readers are referred to Chapter 18 of *Williams Obstetrics*, 25th edition (Hoffman, 2018).

Developmental Anomalies

Congenital malformations of the müllerian duct also may have adverse pregnancy effects. Anomalies include unicornuate, bicornuate, septate, arcuate, and didelphic uteri. Cited prevalence rates for müllerian anomalies vary widely. This likely reflects differences in criteria to define normalcy and in the diagnostic modality employed. Anomalies are often first detected by HSG or routine TVS. Further characterization by 3-dimensional TVS (3-D TVS) and MR imaging may be helpful (Fig. 2-25, p. 42).

In one study of more than 573,000 women, the observed incidence was 1 anomaly in 600 fertile women and 1 in 30 infertile women. The overall incidence was 1 in 200 (Nahum, 1998). Much higher rates are reported using 3-D TVS, perhaps due to its greater sensitivity. Salim and associates (2003) described nearly 2500 women using 3-D TVS. Anomalies were identified in 24 percent of women with RPL, but in only 5 percent of controls. Authors of one metaanalysis concluded that uterine anomalies are present in approximately 17 percent of patients with RPL, 7.3 percent of infertile women, and 6.7 percent of women in the general population (Saravelos, 2008).

The distribution of anomalies and associated loss rates are shown in Table 6-7. Unicornuate, bicornuate, and septate uteri are all associated with increased early miscarriage and second-trimester loss, fetal malpresentation, and preterm labor rates (Reichman, 2010).

TABLE 6-7. Estimated Prevalence of Some Congenital Uterine Malformations and Their Associated Pregnancy Loss Rate

Uterine Anomaly[a]	Proportion (%)	SAB Rate (%)[b]
Bicornuate	39	40–70
Septate or unicornuate	14–24	34–88
Didelphys	11	40
Arcuate	7	—
Hypo- or aplastic	4	—

[a]Estimated overall prevalence 1:200 women (Nahum, 1998).
[b]Includes first- and second-trimester spontaneous abortions (SABs).
Data from Buttram, 1979; Nahum, 1998; Reddy, 2007; Valli, 2001.

Improving early pregnancy outcome by uterine anomaly correction has proved difficult. Nevertheless, in one observational study, pregnancy outcomes were reviewed following hysteroscopic removal of a septum in women with more than two prior miscarriages (Saygili-Yilmaz, 2003). The miscarriage rate declined from 96 to 10 percent following surgery, and the term pregnancy rate rose from 0 to 70 percent. Another metaanalysis reported that hysteroscopic septum resection was associated with a markedly reduced probability of spontaneous abortion compared with untreated women (Venetis, 2014). Based on these reports and the relative safety of surgical correction, most experts recommend hysteroscopic resection of a uterine septum in women with RPL (American Society for Reproductive Medicine, 2012). The procedure is described in Section 44-16 (p. 1065).

In contrast, surgical repair of a bicornuate uterus requires laparotomy and full-thickness incision of the uterine wall (Fig. 19-12, p. 423). Disadvantages to uterine metroplasty include the requirement of cesarean delivery to prevent uterine rupture in subsequent pregnancy. This surgery also is linked to a high rate of postoperative pelvic adhesion formation and subsequent infertility. Thus, uterine metroplasty is generally not recommended except for women who have had a very high number of pregnancy losses. Additional discussion regarding the incidence, clinical impact, and treatment of congenital anatomic abnormalities can be found in Chapter 19 (p. 419). The use of a gestational carrier may be an option in women who are not surgical candidates or for whom surgery is unsuccessful.

Immunologic Factors

The immune system also plays an important role in RPL. Yetman and Kutteh (1996) estimated that 15 percent of more than 1000 women with recurrent miscarriages had recognized immunologic factors. Two primary pathophysiologic models are the *autoimmune theory*—immunity against "self," and the *alloimmune theory*—immunity against antigens from another person.

Autoimmune Factors

RPL has a long-recognized association with systemic lupus erythematosus (Clowse, 2008). Subsequently, many women with lupus were identified to have antiphospholipid antibodies—a family of autoantibodies directed against phospholipid-binding plasma proteins (Erkan, 2011). Between 5 and 15 percent of women with RPL have clinically significant antiphospholipid antibodies compared with only 2 to 5 percent of controls (Branch, 2010).

These antiphospholipid antibodies in conjunction with specific clinical findings are termed the *antiphospholipid antibody syndrome—APS* (American College of Obstetrics and Gynecology, 2017c). Criteria for its diagnosis are shown in Table 6-8. Positive tests are repeated at a minimum of 12 weeks with strict requirements for acceptable laboratory methods and interpretation (Miyakis, 2006). This is the only autoimmune disorder that is clearly linked to pregnancy loss. Miscarriage

TABLE 6-8. Clinical and Laboratory Criteria for Diagnosis of Antiphospholipid Antibody Syndrome[a]

Clinical Criteria
Obstetric:
One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks,
or
Severe preeclampsia or placental insufficiency necessitating delivery before 34 weeks,
or
Three or more unexplained consecutive spontaneous abortions before 10 weeks
Vascular: One or more episodes of arterial, venous, or small vessel thrombosis in any tissue or organ
Laboratory Criteria[b]
Presence of lupus anticoagulant according to guidelines of the International Society on Thrombosis and Hemostasis,
or
Medium or high serum levels of IgG or IgM anticardiolipin antibodies,
or
Anti-β2 glycoprotein-I IgG or IgM antibody

[a]At least one clinical and one laboratory criteria must be present for diagnosis.
[b]These tests must be positive on two or more occasions at least 12 weeks apart.
IgG = immunoglobulin G; IgM = immunoglobulin M.
Modified from Branch, 2010; Erkan, 2011; Miyakis, 2006.

due to APS most often occurs after 10 weeks. APS is more commonly associated with fetal death, preterm delivery, early-onset preeclampsia, and fetal-growth restriction stemming from placental insufficiency and placental thromboses (Clark, 2007a,b).

The mechanisms by which antiphospholipid antibodies result in miscarriage are unclear but can be divided into three general categories—thrombosis, inflammation, and abnormal placentation (Meroni, 2010). With *thrombosis,* it has been proposed that antiphospholipid antibodies act on trophoblast and endothelial surfaces to inhibit annexin A5 function. Annexin A5 is a natural anticoagulant that prevents the activation of factor X and prothrombin (Rand, 2010). Antiphospholipid antibodies may also activate complement to intensify hypercoagulability, which leads to recurrent placental thromboses. *Acute local inflammatory responses* at the placental–maternal interface also may be induced by antiphospholipid antibodies. Last, *placentation* may be affected directly by these antibodies through impaired decidual expression of integrins and cadherins. This can inhibit placental proliferation and syncytial development. Notably, defective decidual trophoblast invasion—not placental thrombosis—is the most common histologic abnormality identified in APS-related early pregnancy loss (Di Simone, 2007).

Several other *antilipid antibody idiotypes* have been described (Bick, 2006). Their measurement is expensive and frequently poorly controlled, and the relevance of results in the evaluation of RPL is uncertain. Results are likewise inconclusive regarding testing for other antibodies including rheumatoid factor, antinuclear antibodies, and those for celiac disease. Currently, testing for these additional antibodies is not recommended during RPL evaluation.

Antiphospholipid Antibody Syndrome Treatment. Various treatments have been proposed for women with APS and RPL (Kutteh, 2014). Studies have compared single-agent or combination therapies using unfractionated heparin, low-molecular-weight heparin (LMWH), low-dose aspirin, glucocorticoids, or intravenous immunoglobulin (IVIG). Concomitant use of glucocorticoids and heparin generally is not recommended. Compared with single-treatment regimens, this combination may increase the maternal fracture risk without improving outcome. In addition, IVIG is not endorsed for RPL.

For women with APS, one reviewer group concluded that the combination of unfractionated heparin and low-dose aspirin significantly benefitted pregnancy outcome in those with prior first-trimester pregnancy losses (Ziakas, 2010). They found no improvement with LMWH and aspirin combinations. Similar conclusions were reached in a Cochrane Database Review (Empson, 2012).

Guidelines from the American College of Obstetricians and Gynecologists (2018b) suggest that women with RPL and APS who have not had a thrombotic event receive prophylactic low-dose aspirin—81 mg orally per day—and heparin when pregnancy is diagnosed. This is continued until delivery and 6 weeks postpartum. Heparin regimens vary, but unfractionated heparin—5000 to 10,000 units subcutaneously daily—is common. Some experts suggest initiating low-dose aspirin prior to conception (Kutteh, 2014). At a minimum, careful clinical surveillance to ensure early pregnancy identification seems prudent.

Alloimmune Factors

The immune tolerance of the mother to a semiallogeneic fetus remains incompletely understood (Williams, 2012). An attractive theory suggests that normal pregnancy requires the expression of blocking factors that prevent maternal rejection of paternally derived foreign fetal antigens. The pregnant woman ostensibly will not produce these blocking factors if she shares human leukocyte antigens (HLAs) with the father.

Other alloimmune disorders that have been posited to cause recurrent miscarriage include altered natural killer cell activity and increased levels of lymphocytotoxic antibodies.

Various tests and treatment options have been developed to address this issue. None has withstood rigorous scrutiny. In an attempt to correct the dysregulated response to fetal antigens, proposed therapies include paternal or third-party leukocyte immunization and IVIG. Three randomized clinical trials failed to demonstrate any benefit of IVIG or placebo in patients with idiopathic miscarriage (Stephenson, 2010). A 2014 Cochrane Review concluded that none of the studied immunotherapies provided a significant benefit over placebo in improving live birth rate or lowering the future miscarriage risk of women with RPL (Wong, 2014). Consequently, immunotherapy is not recommended for RPL.

Endocrinologic Factors

Luteal Phase Defect

Arredondo and Noble (2006) estimated that 8 to 12 percent of recurrent miscarriages are the result of endocrine factors. The greater incidence of miscarriage in these disorders is most frequently attributed to abnormal folliculogenesis with subsequent abnormal luteal function. This so-called *luteal phase defect (LPD)* is postulated to be associated with inadequate endometrial development at implantation. Treatment for presumed LPD has included progesterone supplementation, hCG administration to enhance corpus luteum function, or ovulation induction with agents such as clomiphene citrate to generate additional corpora lutea. A recent metaanalysis concluded that progestogen treatment may lead to a slight reduction in the number of miscarriages but was based on relatively poor-quality data and mixed study designs (Haas, 2018). At this time, progesterone treatment is not recommended despite its minimal risks and expense. Although controversial for LPD, progesterone supplementation is clearly indicated until 8 to 10 weeks in women who have had a corpus luteum removed surgically (p. 139).

Thyroid Disease

Although the mechanisms by which they may adversely affect early pregnancy remain unclear, thyroid disorders, hyperprolactinemia, diabetes mellitus, and polycystic ovarian syndrome (PCOS) merit discussion. Of these, thyroid disorders have long been suspected to cause early pregnancy loss and other adverse pregnancy outcomes. First, severe iodine deficiency—infrequent in developed countries—is associated with excessive miscarriage rates (Castañeda, 2002). In addition, women with hyperthyroidism have greater risks for both spontaneous abortion and stillbirth (Andersen, 2014).

Thyroid hormone insufficiency is common, but the degree of insufficiency varies. In pregnancy, overt hypothyroidism is rare, but the incidence of subclinical hypothyroidism approximates 2 percent (Casey, 2005). Autoimmune *Hashimoto thyroiditis* is a usual cause, and its incidence and severity accrue with age. Despite this common prevalence, any effects of hypothyroidism on early pregnancy loss remain unclear (Krassas, 2010). That said, De Vivo (2010) reported that subclinical thyroid hormone deficiency may be associated with very early pregnancy loss.

The prevalence of abnormally high serum levels of antibodies to thyroid peroxidase or thyroglobulin is nearly 15 percent in pregnant women (Abbassi-Ghanavati, 2010; Haddow, 2011). Most of these women are euthyroid, but those with clinical hypothyroidism tend to have higher concentrations of antibodies. Even in euthyroid women, however, antibodies are a marker for increased miscarriage risk (Chen, 2011; Thangaratinam, 2011).

In sum, current recommendations suggest that all women with RPL undergo thyroid function testing. This includes antibody testing for anti–thyroid peroxidase antibodies (Amrane, 2019). Overt hypo- or hyperthyroidism should be treated to prevent pregnancy complications. It remains unclear whether patients with subclinical hypothyroidism or thyroid autoimmunity should receive treatment (Vissenberg, 2012). Treatment may be considered in patients with both a TSH level above 2.5 mIU/L and positive antibody testing (American Society for Reproductive Medicine, 2015).

Hyperprolactinemia

Cyclic ovulation may become dysfunctional in response to elevated serum prolactin levels such as occurs with prolactinoma. Prolactin also may have direct effects on the endometrium. Hirahara (1998) reported an increase in the successful pregnancy rate for patients with hyperprolactinemia treated with the dopamine agonist bromocriptine. Although data are few, many experts still suggest measuring prolactin levels in patients with RPL.

Diabetes Mellitus

Type 1 diabetes substantively raises risks for spontaneous abortion and major congenital malformations (Greene, 1999). This directly relates to the degree of periconceptional glycemic and metabolic control. Importantly, this risk is greatly mitigated with optimal metabolic control. The miscarriage rate in women with excellent control rivals that of nondiabetic women (Mills, 1988).

In addition, diabetic women with RPL may also have greater degrees of insulin resistance than diabetic women without miscarriages (Craig, 2002). This suggests that ovarian insulin resistance may be contributory, as discussed next.

Polycystic Ovarian Syndrome

Women with PCOS generally have been considered to carry an elevated miscarriage risk. However, this association has been questioned (Cocksedge, 2009). For example, inhibition of serum luteinizing hormone (LH) during a gonadotropin ovulation-induction cycle failed to improve pregnancy outcomes in a controlled trial. This argues against a role for the elevated LH levels seen in PCOS (Clifford, 1996).

Data implicating hyperinsulinemia in pregnancy loss are somewhat stronger. Insulin modulates insulin-like growth factor actions in the ovary, thereby affecting folliculogenesis and steroid production. Retrospective and case-control studies concluded that metformin (Glucophage) lowered miscarriage rates in women with PCOS (Glueck, 2002; Nawaz, 2010). Metformin lowers hepatic glucose production and enhances insulin sensitivity and thereby lowers insulin levels. However, a

systematic review of randomized trials found no improvement in abortion risk with metformin treatment (Palomba, 2009). At this time, routine metformin treatment for women with PCOS solely to treat pregnancy loss is not recommended.

Thrombophilias

The coagulation cascade can be altered by several single-gene mutations that affect pro- or anticoagulant proteins. Mutations predisposing to thrombosis—collectively termed *thrombophilias*—are caused by mutations of the genes for factor V Leiden, prothrombin, antithrombin, and protein C and protein S. These are described further in Chapter 39 (p. 834). In the past, several of these thrombophilias were suspected to cause RPL. However, large prospective cohort studies have refuted these associations, and testing for these abnormalities for RPL is no longer recommended (American College of Obstetricians and Gynecologists, 2018b; American Society of Reproductive Medicine, 2012).

Evaluation and Treatment

Some considerations for evaluation and management of women with RPL are outlined in Table 6-9. Timing and extent of evaluation is based on maternal age, coexistent infertility, symptoms, and level of patient anxiety. In our view, after a thorough history and clinical examination, a modicum of testing is done that is directed to likely causes. General testing may include parental karyotyping, uterine cavity evaluation, and testing for APS. Screening for inherited thrombophilias, endocrine disorders, or LPD has progressively less support. Evaluation also assesses the potential need for psychologic support (Koert, 2019).

Unfortunately, a putative cause will be identified in only about half of couples with RPL. Empiric treatment for unexplained pregnancy loss is discouraged. Even for those with no explanatory findings, couples are cautiously assured that the chances of successfully achieving a live birth are reasonably good (Branch, 2010). Reassuringly, a large cohort study did not detect higher rates of adverse pregnancy outcomes in patients with a history of RPL. Specific assessed outcomes included congenital anomalies, aneuploidy, neonatal asphyxia, or small-for-gestational-age neonates (Sugiura-Ogasawara, 2019).

Although age dependent, the results shown in Tables 6-5 and 6-6 forecast a reasonable prognosis for a successful subsequent pregnancy even after five recurrent losses. Couples may be anxious to try any treatment. However, the lack of definitive benefits for many of these is carefully considered and appropriate counseling offered.

TABLE 6-9. Tests Used for Evaluation of Couples with Recurrent Pregnancy Loss

Etiology	Diagnostic Evaluation	Possible Therapies
Genetic[a]	Karyotype partners	Genetic counseling, donor gametes
Anatomic[a]	Sonohysterography Hysterosalpingogram MR imaging	Septum transection, myomectomy, or adhesiolysis
Immunologic[a]	Lupus anticoagulant Anticardiolipin antibodies Anti-β2 glycoprotein-I antibody	Heparin + aspirin
Endocrinologic[b]	TSH ± TPOAb Prolactin Fasting glucose, Hgb A_{1c} Day 3 FSH, estradiol Midluteal progesterone	Levothyroxine Dopamine agonist Metformin Counseling Progesterone
Thrombophilic[c]	Antithrombin deficiency Protein C or S deficiency Factor V Leiden mutation Prothrombin mutation	No proven treatment
	Hyperhomocysteinemia	Folic acid
Toxic	Tobacco, alcohol use Exposure to toxins, chemicals Obesity	Eliminate consumption Behavior modification Weight loss

[a]Testing for these disorders is generally supported by the literature and expert opinion. One or a combination of these tests may be indicated.
[b]Ongoing controversy regarding testing. Strongest support for thyroid function testing.
[c]Current recommendations against testing. Included for historic reference.
FSH = follicle-stimulating hormone; MR = magnetic resonance; TSH = thyroid-stimulating hormone; TPOAb = thyroid peroxidase antibody.
Modified from Brezina, 2013; Fritz, 2011; Reddy, 2007.

INDUCED ABORTION

Rates

The term *induced abortion* defines the medical or surgical termination of pregnancy before the time of fetal viability. Definitions to describe its incidence include the *abortion ratio*, which is the number of abortions per 1000 live births, and the *abortion rate*, which is the number of abortions per 1000 reproductive-aged women per year.

The Guttmacher Institute reported that 926,200 abortions were performed in the United States in 2014 (Guttmacher, 2019). The Centers for Disease Control and Prevention (CDC) reported an abortion ratio of 188 in 2015 (Jatlaoui, 2018). Most women selecting induced abortion are in their twenties, and 91 percent of abortions in 2015 were performed at a gestational age ≤13 weeks. Only 1.3 percent was performed at a gestational age ≥21 weeks. Notably, 25 percent of all abortions were early medication abortions. This reflects a 114 percent rise compared with the number of medication abortions reported in 2006 (Jatlaoui, 2018).

Worldwide, an estimated 56 million induced abortions occur each year. Women in developing regions have a higher likelihood to select abortion than those in developed regions. Yet, abortion tends to be safer in countries with higher gross national incomes. An estimated 25 million abortions annually are considered unsafe, and Africa and Latin America carry the highest rates (World Health Organization, 2018). In 2012, unsafe abortion was linked to complications in an estimated 6.9 million women worldwide and to 8 percent of maternal deaths.

Indications

Induced abortions are performed for social, economic, or maternal health indications. Medical and surgical conditions include persistent cardiac decompensation, pulmonary arterial hypertension, advanced hypertensive vascular disease, diabetes with end-stage organ failure, and malignancy.

Abortion in the United States

Legality

The legality of abortion was established by the United States Supreme Court in the case of *Roe v. Wade* in 1973. The Court defined the extent to which states might regulate abortion and ruled that first-trimester procedures must be left to the medical judgment of the physician. After this, the state could regulate abortion procedures in ways reasonably related to maternal health. Subsequent to viability, the state could promote its interest in the potential of human life and regulate and even proscribe abortion, except for the preservation of the life or health of the mother. The legal definition of abortion itself is removal of or termination of a pregnancy prior to viability.

Other legislation soon followed. The 1976 Hyde Amendment forbids use of federal funds to provide abortion services except in cases of rape, incest, or life-threatening circumstances. The effect is that most states do not provide public funds for abortion expenses. However, 16 states fund all or most abortions. At least 13 states restrict abortion coverage by private insurance carriers (Guttmacher, 2019).

The Supreme Court in 1992 reviewed *Planned Parenthood v. Casey* and upheld the fundamental right to abortion but established that regulations before viability are constitutional as long as they do not impose an "undue burden" on the woman. Subsequently, many states have passed legislation that imposes counseling requirements, waiting periods, parental consent or notification for minors, facility requirements, and funding restrictions. One major abortion restriction decision was the 2007 Supreme Court decision that reviewed *Gonzales v. Carhart* and upheld the 2003 Partial-Birth Abortion Ban Act. This was problematic because no medically approved definition describes partial-birth abortion.

The Supreme Court decision of *Whole Woman's Health v. Hellerstedt* decided that two provisions in a Texas law created an undue burden and thus violated the Constitution. The first required a physician who performed abortions to have hospital admitting privileges. The second required clinics that provided abortions to have facilities comparable to an ambulatory surgical center.

More than 400 laws restricting access to abortion have been passed in the United States since 2011 (Inman, 2018). In the first 5 months of 2019, seven states have passed legislation to ban first-trimester abortion. These bans currently are, or are expected to be, held up in court.

Access

A woman's chance of receiving the abortion services that best meet her needs varies considerably by locale (National Academies of Sciences, Engineering, and Medicine, 2018). For example, in a survey of Texas women after drastic family planning funding cuts were instituted, 7 percent of women reported an attempt to self-induce abortion. This is significantly higher than the 2 percent rate reported in a U.S. national survey in 2008 (Grossman, 2014). As a correlate, access to safe, legal abortion is the most effective prevention to maternal morbidity.

The American College of Obstetricians and Gynecologists (2019a,b) calls for increased advocacy to overturn restrictions, improve access, and codify abortion as a fundamental component of women's health care. The College (2014, 2016b) supports the legal right of women to obtain an abortion and considers this a medical matter between a woman and her physician.

Training

Because of abortion controversy, training for residents and postgraduate fellows has been both championed and assailed. The Accreditation Council for Graduate Medical Education mandates that obstetrics and gynecology residency programs must provide abortion training or access to training, and this must be part of the planned curriculum (Accreditation Council for Graduate Medical Education, 2017).

The American College of Obstetricians and Gynecologists (2019b) outlines legislative, institutional, and social barriers to abortion training and supports the use of "opt-out" programs. In these, abortion training is integrated as a standard

part of the residency schedule, but residents with religious or moral objections can decline to participate. The Kenneth J. Ryan Residency Training Program was established in 1999 to improve residency training in abortion and family planning. By 2019, more than 70 Ryan programs have been started in the United States and in Canada. However, one survey of U.S. residency program directors found that abortion training was not available in 5 percent of programs and was optional in 31 percent (Steinauer, 2018). In Canada, up to 15 percent of residents report having limited access to abortion training within their residency (Liauw, 2016).

Other programs teach residents technical aspects through management of early incomplete and missed abortions and through uterine evacuation for fetal death, severe fetal anomalies, and life-threatening maternal medical or surgical disorders (Steinauer, 2005). Freedman and coworkers (2010) rightly emphasize that abortion training should include discussion of the social, moral, and ethical aspects of the procedure.

Formal fellowships in Family Planning are 2-year postgraduate programs. By 2019, these are located in 26 departments of obstetrics and gynecology and in two departments of family medicine. Training includes experience with high-level research and uterine evacuation for induced and spontaneous abortion.

Abortion Providers

The American College of Obstetricians and Gynecologists (2016a) respects the need and responsibility of health-care providers to determine their individual positions on induced abortion. The College also emphasizes the need to provide standard-of-care counseling and timely referral if providers have individual beliefs that preclude pregnancy termination. Up to 97 percent of obstetrician-gynecologists may encounter women seeking an abortion, but only 24 percent reported having performed one in the year from 2016 to 2017 (Grossman, 2019; Stulberg, 2011). Most practitioners help women find an abortion provider (Harris, 2011). In any event, physicians who care for women must be familiar with abortion techniques so that referrals for care and management of complications are appropriate.

Counseling before Abortion

Three basic choices are available to a woman considering an abortion. Women may continue pregnancy with its risks and parental responsibilities, may continue pregnancy with arranged adoption, or may elect pregnancy termination with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information regarding these choices for informed decision making (Templeton, 2011).

ABORTION TECHNIQUES

In the absence of serious maternal medical disorders, abortion procedures can be done in an outpatient setting (Levy, 2019). First-trimester abortion can be performed with either medication or surgery. With medication abortion, surgery and the need for sedation are usually avoided. Medication terminations have lower average costs and may allow for more privacy during the termination.

Surgical Abortion

Surgical abortion methods are predominantly completed transvaginally through an appropriately dilated cervix. Rarely, pregnancies are evacuated transabdominally either by hysterotomy or hysterectomy. Electric vacuum aspiration (EVA) of the uterus is the most commonly used form and is illustrated in Chapter 43 (p. 972). Instead, manual vacuum aspiration (MVA) is done with a cannula that attaches to a handheld syringe for its vacuum source.

Cervical Preparation

Unless a woman presents with an incomplete or inevitable abortion, preoperative cervical softening and dilation is common prior uterine evacuation. Cervical preparation softens and slowly dilates the cervix. Medical or mechanical approaches are available, and both aim to minimize the degree of mechanical dilation and thereby lower cervix or uterine trauma risk. Cervical preparation is also associated with less pain, a technically easier procedure, and shorter operating times (Kapp, 2010).

For pregnancies ≤8 weeks, preprocedural cervical ripening is usually unnecessary. After this time, some recommend that osmotic dilators be placed the day prior or misoprostol given 2 to 4 hours before the procedure (Table 6-10). Adolescents, nulliparas, or women with gestations ≥12 weeks may especially benefit from preoperative cervical preparation (Allen, 2016). For gestational age ≥12 weeks, the type and length of time of cervical preparation varies by clinician, patient, and clinical setting. The Society of Family Planning offers excellent clinical guidelines at www.societyfp.org/home (Fox, 2014; Newmann, 2008).

Of medical options for cervical preparation, many clinicians provide a 400-μg buccal misoprostol dose at least 3 hours before uterine vacuum aspiration (Allen, 2016). For gestational ages >20 weeks, mifepristone, a progesterone antagonist, can be given as a 200-mg oral dose (Fox, 2014; Goldberg, 2015).

Of mechanical options, hygroscopic dilators draw water from cervical tissues and expand to gradually dilate the cervix. One type is derived from various species of *Laminaria* algae that are harvested from the ocean floor (Chap. 43, p. 972). Another is Dilapan-S, which is composed of an acrylic-based gel. Each is available in varying diameters.

Electric Vacuum Aspiration

In this method, also known as *dilation and curettage (D & C)*, a cannula is attached to tubing and an electric-powered vacuum source empties the uterus. Suction aspiration is highly effective and obviates the need for sharp curettage, which carries attendant risks for traumatic injury. To begin, the surgeon first dilates the cervix. The pregnancy is then evacuated by suctioning out the contents. Suction is recommended for gestational ages ≤15 weeks.

Manual Vacuum Aspiration

MVA is accomplished with a suction cannula attached to a self-locking syringe for the suction source. Advantages of MVA are that it is portable, is quieter than EVA, and does not require electricity. However, MVA may be limited by the volume that the aspirator can hold. Thus, at gestational

TABLE 6-10. Suggested Cervical Preparation Regimens for Aspiration and D & E Procedures

EGA	Cervical Preparation
<12 weeks	Consider misoprostol 400 µg buccally 3 hours before procedure if: Age <20 years Nulliparous No prior vaginal delivery
≥12 to <15 weeks	Misoprostol 400 µg buccally 3 hours before procedure if: Age <20 years Nulliparous No prior vaginal delivery
≥15 to <17 weeks	Dilapan-S (quantity: 1–4 for ≥4 hours) Laminaria (quantity: 1–7 for ≥4 hours) ***or*** Misoprostol 400 µg buccally ≥3 hours before procedure
≥17 to <20 weeks	Dilapan-S (quantity: 2–5 for ≥4 hours) *plus* Laminaria (quantity 1 to aid dilator removal) ***or*** Laminaria (quantity: 6–10 usually overnight) ***or*** Misoprostol 400 µg buccally for ≥3 hours; may require repeated doses; generally reserved for highly experienced surgeons
≥20 weeks	May require multiple sets of dilators ± mifepristone or misoprostol

D & E = dilation and evacuation; EGA = estimated gestational age.

ages >9 weeks, MVA procedures are lengthier than EVA ones, because the syringe requires repeated emptying. Time can be shortened by using multiple aspirators, which can be changed out.

The technique employs a hand-operated 60-mL syringe and cannula. A vacuum is created in the syringe attached to the cannula, which is inserted transcervically into the uterus. The vacuum produces suction pressures up to 60 mm Hg. MVA complications are similar to EVA (Goldberg, 2004).

Dilation and Evacuation

Dilation and evacuation (D & E) involves cervical dilation followed by evacuation of the fetus and placenta via a combination of tissue forceps and suction cannula. Unless the cervix is already dilated, preoperative cervical preparation is essential to provide an adequate diameter to evacuate the larger tissue volume. For this, ripening options discussed earlier may require up to 48 hours for sufficient effect (see Table 6-10).

D & E is the most frequently used method for second-trimester uterine evacuation in the United States. For these pregnancies, it is generally safer and faster than labor induction (American College of Obstetricians and Gynecologists, 2017b). In addition, risks for a second procedure to remove retained products are lower with D & E than with labor induction (Bryant, 2011).

Many clinicians routinely perform D & E with sonographic guidance. This guides tissue extraction, directs instrument insertion, and confirms complete tissue evacuation. Bierer or Sopher forceps for tissue extraction are valuable adjuncts and are designed to cause minimal trauma to the surrounding endometrium. D & E completion is confirmed with identification of all fetal parts (four extremities, spine, and calvarium). For missing parts, the uterus can be gently explored with these forceps under sonographic guidance.

Medication Abortion

Throughout history, many natural substances have been given for alleged abortifacient effects. Currently, mifepristone is the most widely used medication for induced abortion (Table 6-11). Two other studied agents are misoprostol and methotrexate. The American College of Obstetricians and Gynecologists and the Society of Family Planning regularly update clinical guidelines for management of medication abortion (American College of Obstetricians and Gynecologists, 2016b).

As noted earlier, mifepristone is a progesterone-receptor antagonist. It primes the myometrium and cervix for prostaglandin activity. Clark and associates (2006) reported that mifepristone causes cervical collagen degradation, possibly from greater matrix metalloproteinase expression. Misoprostol is a PGE_1 analogue that directly stimulates the myometrium. Methotrexate is an antimetabolite that stops cell division. It halts fetal growth and placental implantation. These last two are teratogens, and a commitment to complete the abortion is required once these drugs are given. Methotrexate can lead to pulmonary atresia, craniosynostosis, and limb deficiencies (Hyoun, 2012; Nurmohamed, 2011). With misoprostol, the central nervous system, limbs, genitalia, eye, and palate may be affected (Gonzalez, 1998; Vargas, 2000).

Medication abortion is suitable for women who desire privacy or wish to avoid a procedure, if possible. This approach can be performed safely at home and is well tolerated and

TABLE 6-11. Common Medication Regimens for Early Pregnancy Termination

Mifepristone/Misoprostol
[a]Mifepristone, 200 mg orally followed 24–48 hours later by:
[b]Misoprostol, 400 µg vaginally, buccally, or sublingually

Misoprostol Alone
[c]800 µg vaginally or sublingually, repeated for up to three doses

Methotrexate/Misoprostol
[d]Methotrexate, 50 mg/m^2 intramuscularly or orally followed by:
[e]Misoprostol, 800 µg vaginally in 3–7 days. Repeat if needed 1 week after methotrexate initially given

[a]Doses of 200 versus 600 mg are similarly effective.
[b]Oral route may be less effective; possibly more side effects, namely, nausea and diarrhea. Sublingual route has more side effects than vaginal route. Shorter intervals (6 hours) with PGE_1 given after mifepristone may be less effective than when given >36 hours.
[c]Intervals 3–12 hours given vaginally; 3–4 hours given sublingually.
[d]Efficacy similar for routes of administration.
[e]Similar efficacy when given on day 3 versus day 5.
Data from Borgatta, 2001; Coyaji, 2007; Creinin, 2001, 2007; Fekih, 2010; Guest, 2007; Hamoda, 2005; Honkanen, 2004; Jain, 2002; Kulier, 2011; Pymar, 2001; Raghavan, 2009; Schaff, 2000; Shannon, 2006; von Hertzen, 2003, 2007, 2009, 2010; Winikoff, 2008.

effective through 70 days' gestation. The failure rate quoted in most studies is 3 percent (American College of Obstetricians and Gynecologists, 2016b). Contraindications to medication abortion broadly are a patient's unwillingness to have a procedure in the event of heavy bleeding or ongoing pregnancy; an in situ intrauterine device; a confirmed or suspected ectopic pregnancy; and severe anemia, coagulopathy, or anticoagulant use. Additionally, patients who undergo medication abortion should be committed to returning for a follow-up visit.

Contraindications to mifepristone are current long-term systemic corticosteroid therapy, chronic adrenal failure, or allergy to mifepristone. A known allergy to misoprostol is its main limitation to use. Contraindications to methotrexate are listed in Table 7-3 (p. 168).

Provision of mifepristone requires completion of a manufacturer's patient agreement form (Danco Laboratories, 2016). For providers who want to dispense mifepristone in their practice, the drug is available through a *risk evaluation and mitigation strategy (REMS)* program. REMS are U.S. Food and Drug Administration (FDA)-mandated safety strategies to help manage known medicine risks yet still allow access to the drug's benefits (Danco Laboratories, 2019).

Thorough counseling should include a description of cramping and bleeding during conceptus passage. Bleeding that soaks two or more pads per hour for more than 2 consecutive hours warrants a provider discussion or evaluation. Women without bleeding within 24 hours of taking misoprostol should contact their clinician because they may be at risk of ectopic pregnancy or abortion failure.

Updated labeling by the FDA (2016) now matches evidence-based regimens. For gestations up to 70 days' gestation, labeling recommends that a single 200-mg oral dose of mifepristone be administered in the provider's office. After 24 to 48 hours, an 800-µg buccal dose of misoprostol is taken at home. For most women, the pregnancy is expelled after 2 to 24 hours. A woman is reassessed after 7 to 14 days with TVS or serum β-hCG level to confirm no ongoing pregnancy and medication abortion completion. One study reported that a multilayered sonographic pattern indicated a successful abortion (Tzeng, 2013).

Unnecessary surgical intervention in women undergoing medication abortion can be avoided by the proper interpretation of postabortal sonogram findings. Specifically, if no gestational sac is seen and bleeding is not heavy, intervention is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris. Assessment of the clinical course along with bimanual pelvic examination is generally adequate.

ABORTION CONSEQUENCES

Morbidity and mortality associated with abortion is very low. Potential short-term morbidity of induced abortion includes retained tissue, hemorrhage, and infection, each in approximately equal frequency (Niinimäki, 2009; von Hertzen, 2010). In a review of more than 233,000 medication abortions, 0.65 percent was complicated by significant adverse events. Most of these were an ongoing pregnancy (Cleland, 2013). From one systematic review of first-trimester aspiration, the overall major complications rate was ≤1.0 percent (White, 2015). The rate of any complication leading to an emergency department visit was 2 percent in one California study (Upadhyay, 2015).

Complication rates rise with increasing gestational age in both spontaneous and induced abortions. For example, retained tissue occurs more frequently following second-trimester loss (40 percent) compared with earlier losses (17 percent) (van den Bosch, 2008).

Mortality rates from induced abortion performed by trained clinicians, especially during the first 2 months of pregnancy, are less than 1 death per 100,000 procedures (Grimes, 2006; Jatlaoui, 2018). Moreover, pregnancy-associated mortality is 14-fold greater than abortion-related mortality (8 versus

0.6 deaths per 100,000) (Raymond, 2012). Early abortions are even safer, and the relative mortality risk of abortion approximately doubles for each 2 weeks after 8 weeks' gestation. The CDC identified six abortion-related deaths in the United States in 2014 (Jatlaoui, 2018).

Most modern studies and systematic reviews conclude that first-trimester medication and vacuum aspiration abortion do not raise rates of preterm birth in subsequent pregnancies (Kc, 2017; Moreau, 2005; Shah, 2009). Rates of infertility or ectopic pregnancy also are not significantly higher after induced abortion (Atrash, 1997; Shannon, 2004; Stubblefield, 1984). Exceptions may stem from postabortal infections, especially those caused by chlamydial species. It may be most reasonable to compare women undergoing a pregnancy termination with those having a first-trimester miscarriage. In this later group, the 5-year live-birth rate approximates 80 percent (Smith, 2009).

Schneider and associates (1991) described 21 cases in which women who had a hygroscopic dilator placed changed their minds. Of 17 women who chose to continue their pregnancy, 14 carried to term, two delivered preterm, and one miscarried 2 weeks later. None suffered infection-related morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis*. In spite of this generally reassuring report, it seems prudent to presume irrevocability with regard to dilator placement and abortion.

Induced abortion does not negatively affect a woman's mental health. The Turnaway Study is a prospective longitudinal study that followed more than 500 women for 5 years after having obtained or been denied an abortion. Findings showed that induced abortion does not increase a woman's risk of posttraumatic stress, depression, anxiety, low self-esteem, or poor life satisfaction (Biggs, 2017). Effects of being denied an abortion may be more detrimental to psychologic well-being than obtaining a wanted procedure. Modern prospective studies report no association between breast cancer and induced abortion (American College of Obstetricians and Gynecologists, 2018b).

POSTABORTAL CONTRACEPTION

Ovulation may resume as early as 2 weeks after an early pregnancy loss, whether spontaneous or induced. Accordingly, effective contraception should be initiated soon after abortion unless another pregnancy is desired immediately. An intrauterine device can be inserted after the procedure is completed (Bednarek, 2011; Shimoni, 2011). Alternatively, any of the hormonal contraceptive methods discussed in Chapter 5 can be initiated at this time (Madden, 2009; Reeves, 2007).

EPIDEMIOLOGY

An ectopic or extrauterine pregnancy is one in which the blastocyst implants anywhere other than the endometrial lining of the uterine cavity. Nearly 95 percent of ectopic pregnancies implant in the fallopian tube. Other sites are shown in Figure 7-1, which reflects data from 1800 surgically treated ectopic pregnancies (Bouyer, 2002). Rare, bilateral ectopic pregnancies have been described (al-Awwad, 1999).

The reported incidence of ectopic pregnancy is usually calculated as the number of treated cases divided by the total of all pregnancies. Nationally, the rates in 2013 from one large private insurance database and from Medicaid claims were 1.54 percent and 1.38 percent, respectively (Tao, 2017). Stulberg and coworkers (2014) reviewed Medicaid data from 2004 to 2008 from 14 states and found a similar national rate.

Although ectopic pregnancy accounts for a small proportion of all pregnancies, it disparately accounts for 3 percent of all pregnancy-related deaths (Creanga, 2017). Still, current diagnostic and treatment protocols have substantially lowered fatality rates. One analysis showed a 56-percent decline in the ectopic pregnancy mortality ratio between the 1980 to 1984 epoch and the 2003 to 2007 epoch (Creanga, 2011). From the same Medicaid database noted earlier, Stulberg and coworkers (2016) noted that 53 percent of ectopic-related deaths occurred in black women. Inadequate access to gynecologic and prenatal care may partially explain this trend.

RISK FACTORS

Several risks have been linked with ectopic pregnancy. As shown in Table 7-1, abnormal fallopian tube anatomy that alters normal embryo transport underlies most cases. For example, prior tubal pregnancy raises risks. In one study of more than 1000 treated ectopic pregnancies, the recurrence rate was 10 percent (de Bennetot, 2012). Surgeries for fertility restoration, for ectopic pregnancy, or for sterilization also confer a higher risk.

Pelvic inflammatory disease (PID) originating from *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is a potent risk factor for tubal injury and ectopic pregnancy. Recurrent chlamydial infection causes intraluminal inflammation, subsequent fibrin deposition, and tubal scarring (Hillis, 1997). Moreover, persistent chlamydial antigens can trigger a delayed hypersensitivity reaction with continued injury despite negative culture results (Toth, 2000). *N gonorrhoeae* induces a potent acute inflammatory neutrophil influx, which raises levels of destructive matrix metalloproteinases (Stevens, 2018). These lytic enzymes damage and scar fallopian tubal epithelium.

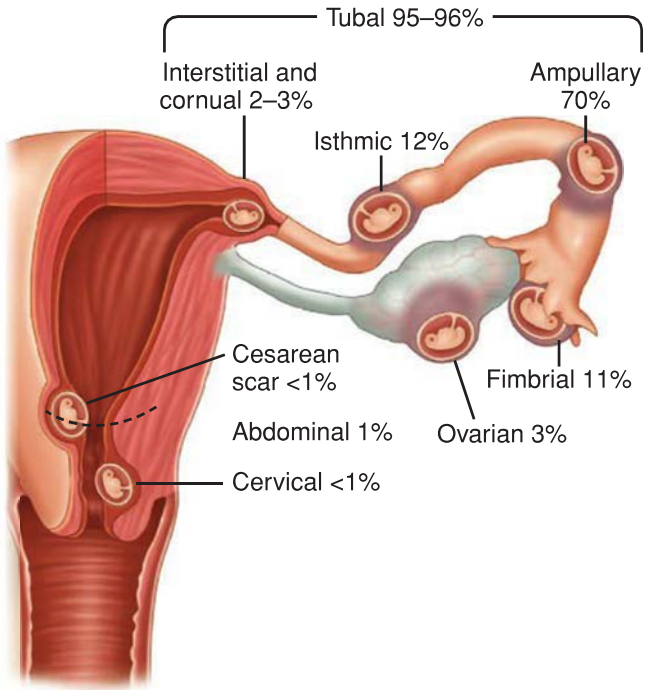

FIGURE 7-1 Various sites and frequency of ectopic pregnancies.

TABLE 7-1. Risk Factors for Ectopic Pregnancy

Factor	Odds Ratio (95% CI)
Prior ectopic pregnancy	12.5 (7.5, 20.9)
Prior tubal surgery	4.0 (2.6, 6.1)
Smoking >20 cigarettes per day	3.5 (1.4, 8.6)
PID confirmed by laparoscopy or positive test for *Chlamydia trachomatis*	3.4 (2.4, 5.0)
≥3 prior miscarriages	3.0 (1.3, 6.9)
Age ≥40 years	2.9 (1.4, 6.1)
Prior medical or surgical abortion	2.8 (1.1, 7.2)
Infertility >1 year	2.6 (1.6, 4.2)
Lifelong sexual partners >5	1.6 (1.2, 2.1)
Prior IUD use	1.3 (1.0, 1.8)

IUD = intrauterine device; PID = pelvic inflammatory disease; STD = sexually transmitted disease.
Data from Bouyer, 2003; Buster, 1999.

Smoking elevates the ectopic pregnancy risk more than threefold in women who smoke more than one pack of cigarettes daily (Saraiya, 1998). Among smokers undergoing assisted reproductive technology, the risk of ectopic pregnancy was 15 times higher in one metaanalysis (Waylen, 2009). The mechanism of this association is unclear, but smoking alters fallopian tube physiology and may affect embryo transport (Shaw, 2010).

Assisted reproductive technology (ART) confers an increased risk for ectopic pregnancy. In women undergoing in vitro fertilization (IVF), the main risk factor for ectopic pregnancy is tubal factor infertility (Li, 2015a). Perkins and associates (2015) reviewed nearly 600,000 pregnancies from 2001 to 2011 conceived by IVF and found a 1.7-percent rate of ectopic pregnancy. Some newer practices are associated with slightly fewer extrauterine implantations. For example, with fresh, nondonor transfers, the ectopic rate drops as the number of embryos transferred is reduced. Also, the transfer of day-5 or day-6 embryos compared with day-3 embryos lowers ectopic pregnancy risk (Du, 2017; Fang, 2015). Last, transfer of frozen-thawed embryos rather than fresh embryos leads to decreased rates (Londra, 2015). Importantly, "atypical" implantation—that is, interstitial, abdominal, cervical, ovarian, or heterotopic—is more common following ART procedures.

Increasing maternal age raises risks of ectopic pregnancy, and patients older than 40 carry the highest risk (Tao, 2017). This has been attributed to age-related hormonal changes that alter tubal function (Coste, 2000).

Contraception lowers overall pregnancy rates and thereby lowers the risk of ectopic pregnancy. However, if pregnancy does occur, some methods increase the relative incidence of ectopic pregnancy (Li, 2014a). Examples include the levonorgestrel-releasing intrauterine system (LNG-IUS) and copper intrauterine device (IUD). In one study of 61,448 IUD users, only 118 contraceptive failures were reported, but 21 of these (18 percent) were ectopic pregnancies (Heinemann, 2015). Progestin-only contraceptive pills also pose a slightly greater risk because of their effects to diminish tubal motility.

If pregnancy occurs after tubal sterilization, the ectopic risk accrues as the time from primary surgery increases. This risk is also greater if electrosurgery methods were used (Malacova, 2014; Peterson, 1997). Although the Essure device for transcervical sterilization has been withdrawn from the U.S. market, many women still rely on this method. In one study, only nine of 722 contraceptive failures (1.25 percent) were ectopic pregnancies (Perkins, 2016).

Altered tubal anatomy can stem from peritubal adhesions subsequent to salpingitis, appendicitis, endometriosis, or other intraabdominal inflammatory processes. Anatomy is also altered with salpingitis isthmica nodosa. In this condition, epithelium-lined diverticula extend into a hypertrophied muscularis layer (Bolaji, 2015; Kutluay, 1994). Finally, congenital fallopian tube anomalies, especially those secondary to in utero diethylstilbestrol exposure, can predispose (Hoover, 2011).

PATHOPHYSIOLOGY

Once normal tubal transport has been disrupted, outcomes of ectopic pregnancy include *tubal rupture*, *tubal abortion*, or *pregnancy failure* with resolution. With tubal rupture, the invading trophoblast and associated hemorrhage tear rents in the fallopian tube. In this genesis, fallopian tube anatomy plays an important role. Specifically, the fallopian tube lacks a submucosal layer beneath its epithelium (Senterman, 1988). Therefore, a fertilized ovum can easily burrow through the epithelium and implant within the tube's muscularis layer (Fig. 7-2). As rapidly proliferating trophoblasts erode the muscularis layer, maternal blood pours into the spaces within the trophoblastic or the adjacent tissue. Rupture is usually spontaneous but can also follow trauma such as that associated with bimanual pelvic examination or coitus.

With tubal abortion, the pregnancy instead may pass out the distal fallopian tube. This outcome depends in part on the initial implantation site, and distal implantations are favored. Subsequently, hemorrhage may cease and symptoms eventually disappear. However, bleeding can persist as long as some products remain in the tube.

With spontaneous failure, the pregnancy dies and is reabsorbed. Of ectopic pregnancies that fail, β-human chorionic gonadotropin (hCG) levels typically are low and likely reflect dying trophoblast.

After tubal implantation, ectopic pregnancy development may follow an acute or chronic course. *Acute ectopic pregnancy* is more common and follows the pathogenesis described in the prior paragraphs. Compared with chronic ectopic pregnancy, acute ectopic pregnancy has higher serum β-hCG levels at initial presentation. The absolute depth of trophoblast invasion into the tubal wall and tubal wall rupture correlates with these high serum levels (Erol, 2015). Also with the acute form, their rapid growth leads to an immediate diagnosis from painful tubal distention or from rupture. Indeed, compared with chronic ectopic pregnancy, acute ectopic pregnancy carries a higher risk of tubal rupture (Barnhart, 2003c).

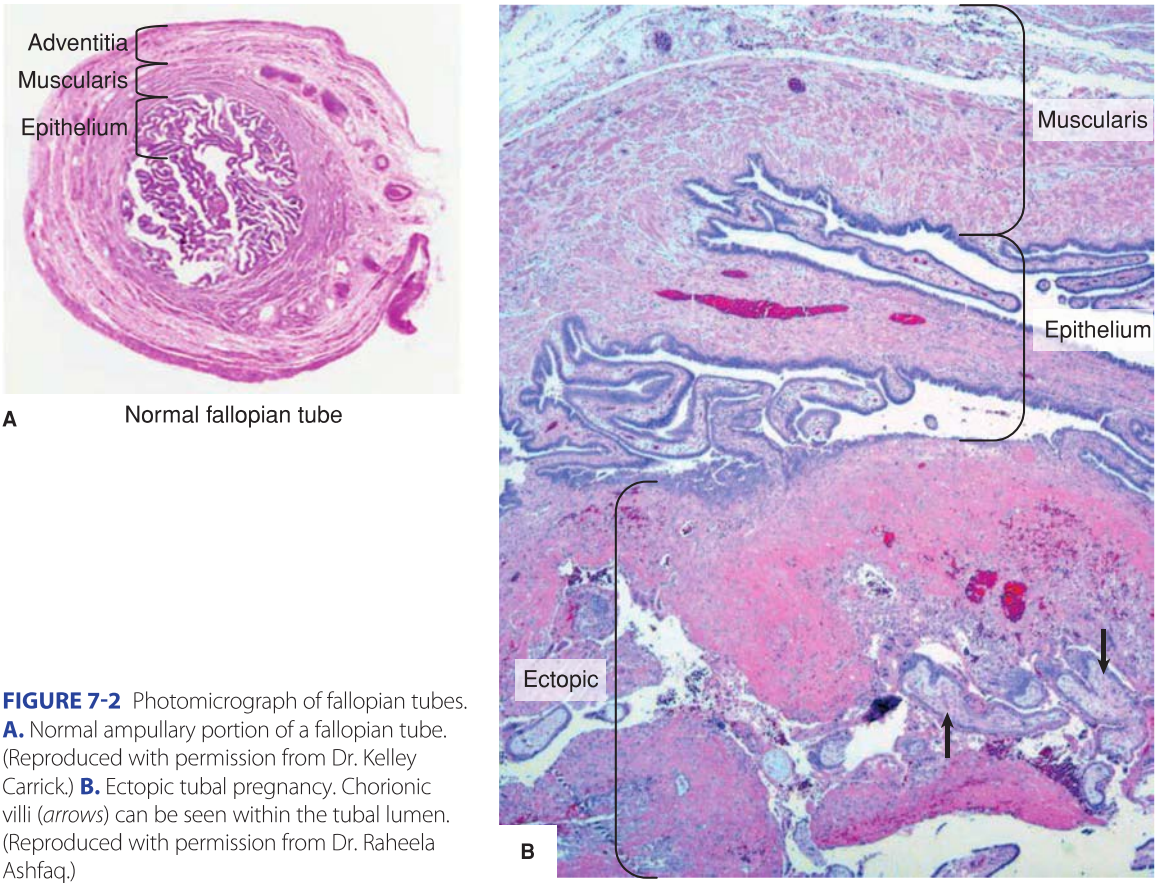

FIGURE 7-2 Photomicrograph of fallopian tubes. **A.** Normal ampullary portion of a fallopian tube. (Reproduced with permission from Dr. Kelley Carrick.) **B.** Ectopic tubal pregnancy. Chorionic villi (*arrows*) can be seen within the tubal lumen. (Reproduced with permission from Dr. Raheela Ashfaq.)

Chronic ectopic pregnancy is much less common. Minor repeated ruptures or tubal abortion incites an inflammatory response that leads to formation of a pelvic mass. This mass contains old blood and gestational tissue surrounded by adhesions. Trophoblastic tissue dies early, and β-hCG testing may be negative or may show very low, static levels. Chronic ectopic pregnancies typically rupture late, if at all, but commonly form a complex pelvic mass. This often is the indication that prompts diagnostic surgery (Cole, 1982; Uğur, 1996).

CLINICAL MANIFESTATIONS

The classic symptom triad of ectopic pregnancy is amenorrhea followed by vaginal bleeding and ipsilateral abdominal pain. However, as women seek care earlier, the ability to diagnose ectopic pregnancy before rupture—even before the onset of symptoms—is not unusual. Of other symptoms, banal pregnancy discomforts such as breast tenderness and nausea may accompany more ominous findings. These include shoulder pain worsened by inspiration, which is caused by phrenic nerve irritation from subdiaphragmatic blood. Vasomotor disturbances such as vertigo and syncope may reflect hemorrhage-related hypovolemia.

Of physical findings, some hypovolemic women show orthostatic changes, and the shock index is one evaluation tool. This index is calculated as the heart rate divided by systolic blood pressure and can assess trauma patients for hypovolemic or septic shock. The normal range lies between 0.5 and 0.7 for nonpregnant patients. A shock index >0.85 and a systolic blood pressure <110 mmHg are highly suggestive of a potentially life-threatening gynecologic emergency, such as a ruptured ectopic pregnancy (Birkhahn, 2003; Polena, 2015). Despite these findings of advanced hypovolemia, normal vital signs are unreliable to exclude earlier stages of tubal rupture and blood loss.

Abdominal and pelvic findings may also be notoriously few in women before tubal rupture. With rupture, however, many will have marked tenderness on both abdominal and pelvic examination, and pain is aggravated with cervical manipulation. A pelvic mass, including fullness posterolateral to the uterus, can be gently palpated in some affected women. Initially, an ectopic pregnancy may feel soft and elastic, whereas extensive intraluminal hemorrhage produces a firmer consistency. Many times, discomfort precludes palpation of the mass, and limiting examinations may help avert iatrogenic rupture.

DIAGNOSIS

Ectopic pregnancy is considered in any reproductive-aged woman with pain, uterine bleeding, and/or anemia. Symptoms of ectopic pregnancy can mimic multiple entities (Table 12-1, p. 255). Broadly, these can first be divided into complications of early pregnancy or not. Thus, in those without prior hysterectomy, urine pregnancy testing is indicated. If testing is positive, transvaginal sonography and serial serum β-hCG measurements are the most valuable diagnostic aids. Additionally, because ectopic pregnancy can lead to significant bleeding, a hemogram is an additional fast and effective initial screen.

Laboratory Findings

Serum β-hCG Measurements

Human chorionic gonadotropin is a glycoprotein produced by syncytiotrophoblast of the placenta and can be detected in serum as early as 8 days after the luteinizing hormone (LH) surge. Current pregnancy tests have lower limits of detection that are 20 to 25 mIU/mL for urine and ≤5 mIU/mL for serum (Greene, 2015). Importantly, given an interassay variability of 5 to 10 percent, interpretation of serial values is more reliable when performed by the same laboratory (Desai, 2014).

With a robust intrauterine pregnancy (IUP), early studies suggest that serum β-hCG levels should rise at least 53 to 66 percent every 48 hours (Barnhart, 2004; Kadar, 1982). A more conservative rise of 35 percent in 48 hours is now often used, and this lowers the potential disruption of normal IUPs (Seeber, 2006). With multifetal gestation, this same anticipated rate of rise is expected (Chung, 2006).

Importantly, a similar 53-percent or greater rise at 48 hours can be seen with ectopic pregnancy cases (Silva, 2006). Moreover, inadequately rising serum β-hCG levels indicate only a dying pregnancy, not its location. Thus, β-hCG levels are coupled with sonography and other clinical findings.

Past this 48 hours, adding a third serum β-hCG level on day 4 or 7 may better determine the location and viability of the pregnancy (Morse, 2012; Zee, 2014). This is weighed against an increased chance of ectopic pregnancy rupture during these extra diagnostic days.

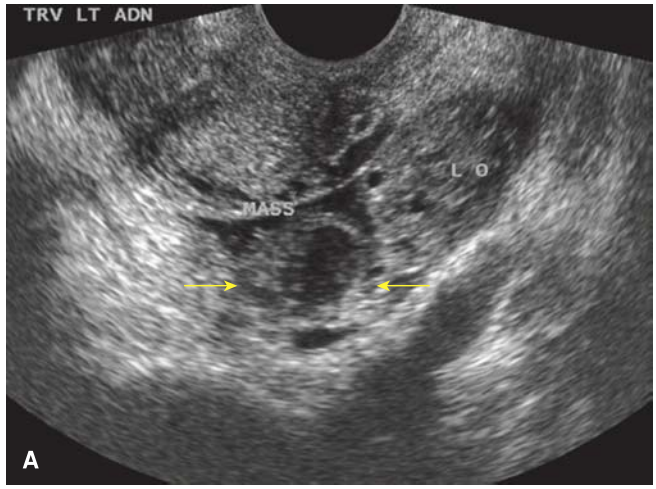
Serum Progesterone Levels

Serum progesterone concentration is used by some to aid ectopic pregnancy diagnosis when serum β-hCG levels and sonographic findings are inconclusive (Stovall, 1992). Serum progesterone concentration varies minimally between 5 and 10 weeks' gestation, thus a single value is sufficient. From studies, a single serum progesterone level <6 ng/mL (<20 nmol/L) has a specificity of 99 percent to predict a nonviable pregnancy in women without clear sonographic evidence of pregnancy location (Van Calster, 2016; Verhaegen, 2012). Ultimately, serum progesterone levels can be used to buttress a clinical impression, but again they cannot reliably differentiate between ectopic and intrauterine pregnancies (Guha, 2014).

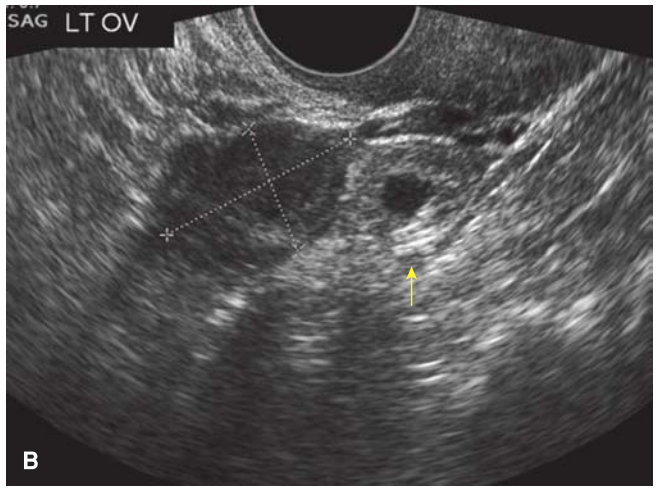
Sonography

High-resolution sonography has revolutionized the management of women with a suspected ectopic pregnancy. With transvaginal sonography (TVS), an intrauterine gestational sac is usually visible between 4½ and 5 weeks, the yolk sac appears between 5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5½ to 6 weeks. With transabdominal sonography, these structures are visualized slightly later. The sonographic diagnosis of ectopic pregnancy rests on visualization of an adnexal mass separate from the ovary (Fig. 7-3). Definitive criteria include either an extrauterine yolk sac or embryo.

When ectopic pregnancy is part of a differential diagnosis, serum β-hCG testing is used to define expected sonographic findings. Each institution must define a β-hCG discriminatory value for TVS, that is, the lower limit at which an examiner can



Inhomogeneous mass



Mass with empty extrauterine sac

Mass with yolk sac

FIGURE 7-3 Transvaginal sonographic findings with various ectopic pregnancies. For sonographic diagnosis, an ectopic mass should be seen in the adnexa separate from the ovary and may be seen: **(A)** as an inhomogeneous adnexal mass (*yellow arrows*), **(B)** as an empty extrauterine sac with a hyperechoic ring (*arrow*), or **(C)** as a yolk sac and/or fetal pole with or without cardiac activity within an extrauterine sac. reliably visualize an IUP. Early threshold values were ≥1500 or ≥2000 mIU/mL, but others subsequently have suggested an even higher threshold (Barnhart, 1994; Mehta, 1997). Specifically, Connolly and associates (2013) noted that with live IUPs, a gestational sac was seen 99 percent of the time with a discriminatory level of >3510 mIU/mL. The American College of Obstetricians and Gynecologists (2018) recognizes this more conservative threshold. Even with β-hCG levels above the chosen discriminatory value, technical challenges such as leiomyomas, adenomyosis, multifetal gestation, or IUD can hinder the ability to accurately diagnose an intrauterine gestation (Gurel, 2007; Ko, 2014).

When β-hCG levels are above the set discriminatory value, absence of an IUP may suggest an abnormal pregnancy. These include an ectopic pregnancy, an incomplete abortion, or a resolving completed abortion. For example, despite total passage of products of conception with complete abortion, β-hCG testing may still be positive while original β-hCG is metabolized and cleared. Early multifetal gestation also remains a possibility (Ko, 2014). Without clear evidence for ectopic pregnancy, serial β-hCG level assessment is reasonable in a hemodynamically stable patient. This averts unnecessary MTX administration to a failing IUP and avoids harming an early normal multifetal intrauterine pregnancy.

Conversely, when β-hCG values lie below the discriminatory value, sonographic findings are typically nondiagnostic. With this *pregnancy of unknown location (PUL)*, serial β-hCG level assays are done to identify patterns that indicate either a growing or failing IUP. As noted, thriving IUPs show a minimum 35-percent rise in β-hCG levels after 2 days. Conversely, PULs that ultimately are found to be failing IUPs show a characteristic decline (Table 7-2). Levels that rise or fall outside these expected parameters raise the concern for ectopic pregnancy.

TABLE 7-2. Percentage Decline of Initial Serum β-hCG Levels in Those with PUL and Ultimately Diagnosed with Spontaneous Abortion

	Percentage Decline[a]		
	By Day 2	By Day 4	By Day 7
Initial hCG (mIU/mL)	Expected % (Minimum %)	Expected % (Minimum %)	Expected % (Minimum %)
50	68 (12)	78 (26)	88 (34)
100	68 (16)	80 (35)	90 (47)
300	70 (22)	83 (45)	93 (62)
500	71 (24)	84 (50)	94 (68)
1000	72 (28)	86 (55)	95 (74)
2000	74 (31)	88 (60)	96 (79)
3000	74 (33)	88 (63)	96 (81)
4000	75 (34)	89 (64)	97 (83)
5000	75 (35)	89 (66)	97 (84)

[a]The percentage decline is given as the expected decline. The minimum expected decline in parentheses is the 95th percentile value. Declines less than this minimum may reflect retained either intrauterine or extrauterine trophoblast.
Data from Barnhart, 2004; Chung, 2006.

In an attempt to unify the language used with sonographic evaluation of early pregnancies, a consensus statement was drafted with five categories: (1) definitive ectopic pregnancy (extrauterine gestational sac with yolk sac and/or embryo), (2) probable ectopic pregnancy (inhomogeneous adnexal mass or extrauterine halo-like structure), (3) probable IUP (intrauterine echogenic sac), (4) definite IUP (intrauterine gestational sac with yolk sac and/or embryo), and (5) PUL (lacking signs of either ectopic pregnancy or IUP) (Barnhart, 2011).

Systematic sonographic evaluation is critical to establish the correct diagnosis. Most begin with the endometrial cavity. In pregnancies conceived spontaneously, identification of an IUP effectively excludes the possibility of ectopic implantation. When ART is employed, however, careful examination of the tube and ovary is performed even with an IUP because heterotopic pregnancy rates may be as high as 1 per 1000 (Perkins, 2015). An intracavitary fluid collection caused by sloughing of the decidua can create a *pseudogestational sac*, or *pseudosac*. As shown in Figure 7-4, this one-layer collection typically lies in the midline of the uterine cavity. In contrast, a normal gestational sac is eccentrically located, that is, lying within one side of the endometrial stripe more than the other (Dashefsky, 1988). Another intracavitary finding of ectopic pregnancy is a trilaminar endometrial pattern, which represents two adjacent edematous proliferative-phase endometrial layers (Fig. 2-16, p. 38) (Lavie, 1996). For the diagnosis of ectopic pregnancy, this finding's specificity is 93 percent but sensitivity is only 21 percent (Col-Madendag, 2010). Endometrial stripe thickness has not been well correlated with ectopic pregnancy. However, Moschos and Twickler (2008b) determined that in PULs, none that ultimately proved to be normal IUPs had a stripe thickness <8 mm.

The fallopian tubes and ovaries are also inspected. Seeing an extrauterine yolk sac or embryo clearly confirms an ectopic pregnancy, although such findings are less common (Paul, 2000). In some cases, a *halo* or tubal ring can be seen. This ring surrounds an anechoic center and is covered by a thin hypoechoic

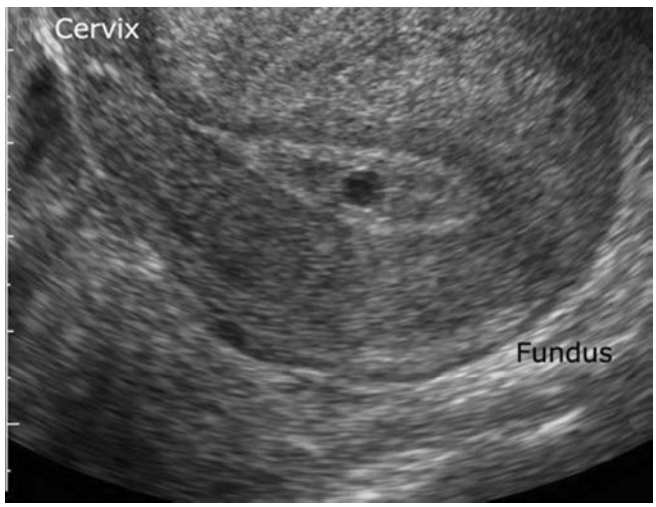

FIGURE 7-4 Transvaginal sonography of a pseudogestational sac within the endometrial cavity. Note its circular shape and central location, which are characteristic of these fluid collections. (Reproduced with permission from Dr. Elysia Moschos.)

area caused by subserosal tubal edema. According to Burry and associates (1993), this has a positive predictive value of 92 percent and a specificity of 95 percent. Alternatively, a more solid, inhomogeneous complex adnexal mass is usually caused by hemorrhage within the ectopic sac or by an ectopic pregnancy that has ruptured into the tube. Overall, approximately 60 percent of ectopic pregnancies are seen as an inhomogeneous mass adjacent to the ovary; 30 percent appear as a hyperechoic ring; and 8 percent have an obvious gestational sac with a fetal pole (Nadim, 2018). In women undergoing sonography for ectopic pregnancy concerns, specificity is 95 to 99 percent and positive predictive value is 96 percent for ectopic pregnancy when an extraovarian adnexal mass is found (Brown, 1994; Nadim, 2018). However, not all extraovarian adnexal masses represent an ectopic pregnancy, and integration of sonographic findings with other clinical information is necessary.

With transvaginal color Doppler imaging, placental blood flow within the periphery of an ectopic pregnancy—the *ring of fire*—can be seen (Fig. 7-5). However, this ring can also be noted with a corpus luteum of pregnancy. Another technique to help characterize a suspicious mass involves an examiner gently palpating an adnexum that is placed between the vaginal probe and the examiner's abdominal hand during real-time scanning. A mass that moves separately from the ovary suggests a tubal pregnancy, whereas a mass that moves synchronously more likely represents an intraovarian structure (Levine, 2007).

Also during sonographic evaluation of the pelvis, TVS can detect as little as 50 mL of free peritoneal fluid in the posterior cul-de-sac (Fig. 7-6). This may be intraabdominal bleeding or physiologic peritoneal fluid. A large volume of fluid or fluid that is echogenic is more worrisome for hemoperitoneum. In addition, transabdominal right upper quadrant sonographic imaging helps assess the extent of hemoperitoneum. Blood in the paracolic gutters and Morison pouch indicates significant hemorrhage. Specifically, free fluid in Morison pouch typically is not seen until a hemoperitoneum reaches 400 to 700 mL (Branney, 1995; Rodgerson, 2001). Detection of peritoneal fluid in conjunction with an adnexal mass and positive pregnancy testing is highly predictive of ectopic pregnancy (Nyberg, 1991). That said, despite technologic advances, the absence of suggestive findings does not exclude ectopic pregnancy. Moreover, in rare instances, an hCG-secreting tumor can produce the triad of adnexal pathology, ascites, and positive hCG testing (Chap. 16, p. 338). Thus, in all circumstances, clinical integration is essential.

FIGURE 7-5 Color Doppler transvaginal sonography of an ectopic pregnancy. The "ring of fire" reflects placental blood flow around the periphery of the pregnancy. This finding, however, may also be seen with corpus luteum cysts.

Culdocentesis

With a 16- to 18-gauge spinal needle, the posterior cul-de-sac can be entered through the posterior vaginal fornix. The aspirate characteristics, in conjunction with clinical findings, may help clarify the diagnosis. Colorless or yellow clear peritoneal fluid is designated as a negative test. If fragments of an old clot or nonclotting blood are found in the aspirate when placed into a dry, clean test tube, then hemoperitoneum is diagnosed. If the aspirated blood clots after it is withdrawn, this may signify

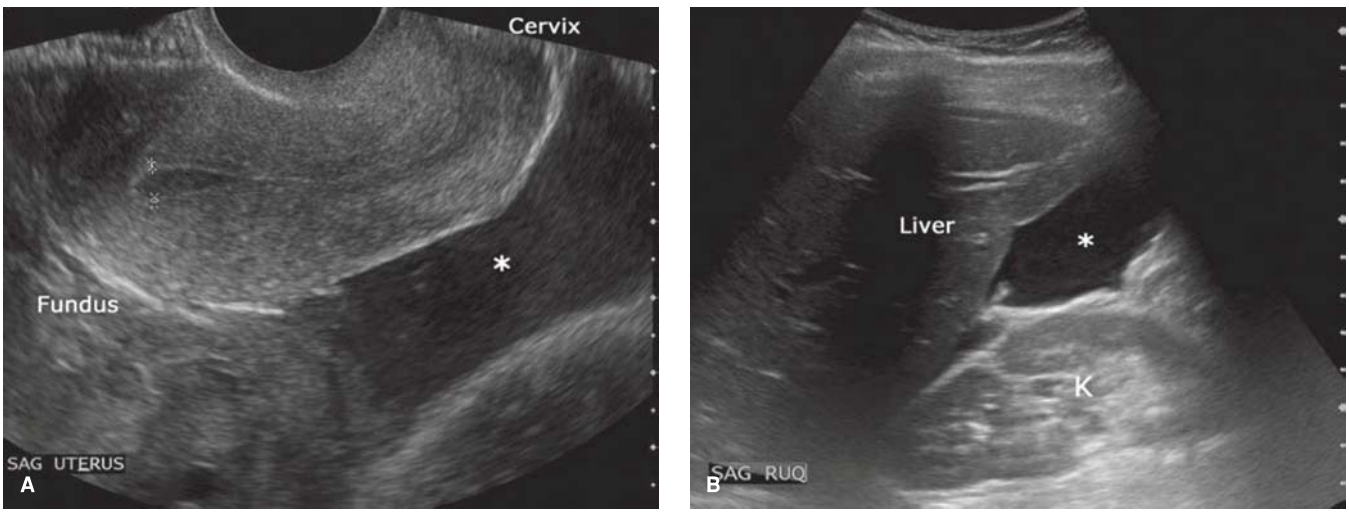

FIGURE 7-6 **A.** Transvaginal sonography displays hypoechoic fluid (*asterisk*) in the posterior cul-de-sac. **B.** Right upper quadrant sonogram shows anechoic fluid (*asterisk*) in Morison pouch between the liver and kidney (*K*).

active intraperitoneal bleeding or puncture of an adjacent vessel. If fluid cannot be aspirated, the test can only be interpreted as unsatisfactory. Purulent fluid suggests an infection-related etiology such as salpingitis or appendicitis. Feculent material may originate from a perforated colon or an inadvertent puncture of the rectum during culdocentesis.

Several studies have challenged the usefulness of this bedside test, and culdocentesis mostly has been replaced by TVS (Glezerman, 1992; Vermesh, 1990). Sonography with findings of echogenic fluid to establish hemoperitoneum is more sensitive and specific than culdocentesis—100 and 100 percent versus 66 and 80 percent, respectively. Also, for most women, sonography is better tolerated.

Endometrial Evidence

Several endometrial changes are associated with ectopic pregnancy. These include decidua found in 42 percent of samples, secretory endometrium in 22 percent, and proliferative endometrium in 12 percent, all with an absence of trophoblast (Lopez, 1994). Decidua is endometrium that is hormonally prepared for pregnancy, and the degree to which the endometrium is converted with ectopic pregnancy is variable. Thus, in addition to bleeding, women with ectopic tubal pregnancy may pass a *decidual cast*, which is the entire sloughed endometrium that takes the form of the endometrial cavity (Fig. 7-7). Decidual sloughing may also occur with an IUP abortion. Thus, tissue is carefully evaluated visually and then histologically for evidence of a conceptus. If no clear gestational sac is visually seen or if no villi are identified histologically within the cast, then the possibility of ectopic pregnancy must still be entertained.

Dilation and curettage (D & C) can help clarify the diagnosis in persistent or unclear PUL cases. Villi in the surgical sample support an intrauterine location. This strives to avoid treating the mother and exposing a potential IUP to methotrexate, a known teratogen (p. 169). Less often, in cases of diagnosed ectopic pregnancy, some also recommend curettage prior to methotrexate treatment to confirm the absence of intrauterine villi (Barnhart, 2002; Chung, 2011; Shaunik, 2011). This averts maternal, and possible IUP, exposure to potential drug side effects. Nevertheless, the need, method, and risks of surgical endometrial sampling must carefully be weighed against the evidence supporting the diagnosis of ectopic pregnancy and drug risks in a given patient.

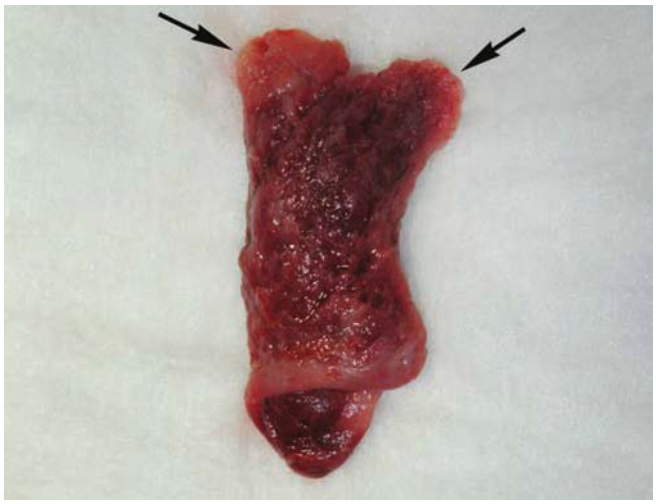

FIGURE 7-7 In this decidual cast, arrows mark the area that conformed to the cornua. (From Hoffman, 2018, with permission.)

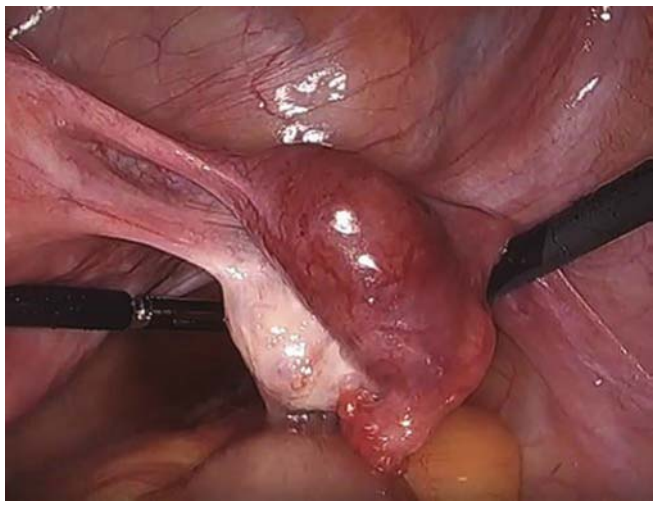

FIGURE 7-8 Laparoscopic photograph of a right-sided ectopic pregnancy shows a distended tubal ampulla. (Reproduced with permission from Dr. Lisa Chao.)

Endometrial biopsy with a Pipelle catheter or endometrial aspiration was studied as an alternative to surgical curettage and found inferior (Barnhart, 2003b; Insogna, 2017). By comparison, frozen section of surgical curettage fragments to identify products of conception is accurate in more than 90 percent of cases (Barak, 2005; Li, 2014b; Spandorfer, 1996).

Summary of Diagnostic Evaluation

Confirmation by diagnostic laparoscopy remains the gold standard for ectopic pregnancy diagnosis (Fig. 7-8). That said, with sensitive diagnostic modalities available, ectopic pregnancy can typically be diagnosed prior to surgery, and use of an evidence-based approach can assist. First, after appropriate clinical evaluation, all reproductive-aged women with any suspicion of pregnancy are tested using a sensitive urine β-hCG assay. Following positive testing, TVS is completed for all women with first-trimester pain or bleeding. If sonographic findings are not diagnostic and concerns for ectopic pregnancy complications are not urgent, serial serum β-hCG levels are measured until discriminatory zone levels are reached. TVS is then repeated. The interval between serum testing after the first 48 hours, however, is currently not well defined. The American College of Obstetricians and Gynecologists (2018) recommends serum β-hCG level testing every 2 to 7 days depending on the level of change. Those with a higher ectopic pregnancy risk are typically tested more frequently. D & C or diagnostic laparoscopy or both can be considered to help clarify cases concerning for, but not clearly diagnostic of, ectopic pregnancy.

Because ectopic pregnancies can rupture even at low β-hCG levels, serum β-hCG values are usually followed until they lie below the "negative" result threshold for the given assay. Rupture at low values likely reflects partial disruption of the

vascular connection between trophoblast and maternal vessels. That said, one recent study of more than 1500 PULs showed that a β-hCG value drop of 85 percent between the initial draw and day-4 values or 95-percent decline by day 7 excluded 100 percent of ectopic pregnancies (Cameron, 2016).

To better define PULs and their ectopic risk, several protocols and risk calculators have been evaluated. These ideally limit overtesting of pregnancies yet still identify high-risk pregnancies for close surveillance (Van Calster, 2013, 2016). These have not been sufficiently validated in United States populations (Barnhart, 2010).

MANAGEMENT

Once diagnosed, ectopic pregnancies can be managed surgically, medically with methotrexate (MTX), or expectantly. Because of the potential for life-threatening bleeding, careful patient selection is essential.

With the ending of any early pregnancy, Rh status is assessed. Alloimmunization is a possibility in D-negative women. Therefore, 300 μg of anti-D immune globulin is given to these women if the father of the baby has the D antigen or if his status is unknown (Krause, 1996).

Medical Management

For most ectopic pregnancies, medical therapy is preferred, if feasible, to avoid surgical risks. However, before consideration of this option, important criteria must be met. Namely, evidence for tubal rupture and hemodynamic instability are absent, and the patient must lack MTX contraindications (Table 7-3). Other considerations include reasonably close access to an emergency department and a commitment to be compliant with surveillance laboratory testing.

Some classic predictors of success with MTX use are the initial serum β-hCG level, ectopic pregnancy size, and fetal cardiac activity. Of these, the β-hCG level is the single best prognostic indicator of treatment success. In their classic study, Lipscomb and colleagues (1999) found that an initial serum value <5000 mIU/mL was associated with a success rate of 92 percent, whereas an initial concentration >15,000 mIU/mL had a success rate of only 68 percent. This trend has been confirmed by many. In a more recent study, the failure rate associated with β-hCG levels >4500 mIU/mL was 65 percent (Cohen, 2014). Although not exclusionary, rapidly rising β-hCG levels in the 48 hours before MTX therapy may also portend a higher failure rate (Cohen, 2017; Dudley, 2004). Specifically, a rise >50 percent is cited by the American Society for Reproductive Medicine (2013) as a predictor.

The effect of size on success rates with medical therapy has fewer supporting data, although many early trials used "large size" as an exclusion criterion. In one study, the success rate with single-dose methotrexate was 93 percent in cases with ectopic masses ≤3.5 cm, whereas success rates were between 87 and 90 percent when the mass was >3.5 cm (Lipscomb, 1998). These authors also found ectopic pregnancies measuring ≤4 cm and lacking cardiac activity to be suitable candidates.

Cardiac activity seen sonographically is also a relative contraindication to medical therapy. Most studies report a greater failure rate if cardiac activity is noted. Still, a success rate of 87 percent has been reported (Lipscomb, 1998).

Methotrexate

This medication stalls cell growth and protein production by competitively inhibiting the enzyme dihydrofolate reductase (Berlin, 1963). Possible MTX side effects include stomatitis, conjunctivitis, transient liver dysfunction, myelosuppression,

TABLE 7-3. Medical Treatment Protocols for Ectopic Pregnancy

	Single Dose	Multidose
Dosing	One dose; repeat if necessary	Up to four doses of both drugs until serum β-hCG declines by 15%
Medication dosage		
Methotrexate	50 mg/m^2 BSA (day 1)	1 mg/kg, days 1, 3, 5, and 7
Leucovorin	NA	0.1 mg/kg days 2, 4, 6, and 8
Serum β-hCG level	Days 1, 4, and 7	Days 1, 3, 5, and 7
Indication for additional dose	• If serum β-hCG level does not decline by 15% from day 4 to day 7 • <15% decline during weekly surveillance	If serum β-hCG declines <15% between days 1 & 3, give additional dose; repeat serum β-hCG in 48 hours and compare with previous value; maximum four doses
Surveillance	Once 15% decline achieved, draw weekly serum β-hCG level until undetectable	

Methotrexate Contraindications		
Sensitivity to MTX	Intrauterine pregnancy	Peptic ulcer disease
Tubal rupture	Hepatic, renal, or hematologic dysfunction	Immunodeficiency
Breastfeeding	Active pulmonary disease	

BSA = body surface area; β-hCG = β-human chorionic gonadotropin; MTX = methotrexate; NA = not applicable.

mucositis, pulmonary damage, and anaphylactoid reactions (Conway, 2015; Salliot, 2009; Shao, 2018; Soysal, 2016; Troeltzsch, 2013). In some cases, leucovorin (folinic acid) is given following treatment to blunt or reverse MTX side effects. Such therapy is termed *leucovorin rescue* and discussed in Chapter 27 (p. 592).

To help select suitable MTX candidates, several laboratory tests are obtained. First, MTX is renally cleared, and significant renal dysfunction precludes its use (Rheumatoid Arthritis Clinical Trial Archive Group, 1995). Thus, a serum creatinine level is reviewed. Second, MTX can be hepato- and myelotoxic, and complete blood count (CBC) and liver function tests (LFTs) establish a baseline. Last, blood type and Rh status are determined. All except blood typing are considered surveillance laboratory tests and are repeated prior to additional MTX doses (Lipscomb, 2007).

With administration, women are counseled to avoid several aggravating agents until treatment is completed. These are: (1) folic acid–containing supplements, which can competitively reduce methotrexate binding to dihydrofolate reductase; (2) nonsteroidal antiinflammatory drugs, which reduce renal blood flow and delay drug excretion; (3) alcohol, which can predispose to concurrent hepatic enzyme elevation; (4) sunlight, which can provoke MTX-related dermatitis; and (5) sexual activity, which can rupture the ectopic pregnancy (American College of Obstetricians and Gynecologists, 2018).

Importantly, MTX is a teratogen that can lead to severe embryopathy including pulmonary atresia, craniosynostosis, and limb deficiencies (Hyoun, 2012; Nurmohamed, 2011). Thus, to avoid inadvertent fetal exposure, MTX is ideally used when a confident diagnosis of ectopic pregnancy is made. PUL is a transition diagnosis and is not suitable for MTX administration.

During the first few days following MTX administration, some abdominal pain is common, and patients are so counseled. This separation pain presumably results from tubal distention caused by tubal abortion or hematoma formation or both (Stovall, 1993). Mild analgesics are typically sufficient. In few cases, inpatient observation with serial hematocrit determinations and gentle abdominal examinations help assess the need for surgical intervention.

Dosing Options

The two most common regimens are listed in Table 7-3, and doses are given IM. With single-dose therapy, the dose is 50 mg/m^2 body surface area (BSA), and BSA can be derived using various Internet-based BSA calculators. At our institution, patients are observed for 30 minutes following MTX injections to exclude adverse reaction.

During single-dose therapy, a serum β-hCG level is measured on the day of MTX administration, and this is repeated on days 4 and 7 following injection. Day-4 levels may rise or fall. Although both trends are acceptable, falling levels are linked to higher resolution rates (Agostini, 2007; Nguyen, 2010; Skubisz, 2013). Next, a comparison is made between day 4 and 7 serum values. If the value declines by ≥15 percent, weekly serum β-hCG levels are then drawn until they measure <2 mIU/mL. A decline <15 percent is seen in approximately 20 percent of treated women. In such cases, a CBC, creatinine level, and LFTs are rechecked. If these surveillance tests are normal, a second IM 50-mg/m^2 dose based on BSA is given. The date of this second injection will become the new day 1, and the protocol is restarted. Others have tried, without success, to develop more convenient, yet reliable, serum β-hCG monitoring protocols (Dai, 2017; Kirk, 2007; Thurman, 2010). In the end, the original day-4-to-7 guidelines have been validated.

Shown in Table 7-3, multidose therapy provides MTX (1 mg/kg) treatment with leucovorin (0.1 mg/kg) therapy on alternating days. A maximum of four doses of MTX can be given, and each is followed by the adjunctive doses of leucovorin 24 hours later. After the first dyad of injections, a serum β-hCG concentration is measured. Values between days 1 and 3 are anticipated to drop by ≥15 percent. If not and if surveillance tests are normal, an additional MTX/leucovorin alternating dyad is given. A serum β-hCG level is repeated 2 days later. Once a decline >15 percent is achieved, weekly serum β-hCG level testing then begins until values are undetectable.

Comparing the efficacy of single- versus multidose MTX, Lipscomb and colleagues (2005) studied 643 consecutively treated patients. They found no significant differences in treatment duration, serum β-hCG levels, or success rates between the multi- and single-dose protocols—95 and 90 percent, respectively. Barnhart and coworkers (2003a) performed a metaanalysis of 26 studies that included 1327 women treated with MTX for ectopic pregnancy. The success rates were 88 percent with single-dose and 92 percent for multidose treatment. Last, in a randomized trial with 70 patients, Tabatabaii and associates (2012) found resolution rates of 83 percent with single-dose and 87 percent with multidose regimens, respectively. At our institution, we use single-dose IM MTX.

A hybrid "two dose" MTX protocol strives to balance the efficacy and convenience of the two most commonly used protocols (Barnhart, 2007). However, comparisons of the single-dose and two-dose MTX protocols found equivalent success rates (Mergenthal, 2016; Song, 2016).

Surveillance

Posttherapy monitoring assesses treatment success and screens for signs of persistent ectopic pregnancy. In the absence of symptoms, bimanual examinations are limited to avoid the theoretical risk of manual tubal rupture. Importantly, sonographic monitoring of ectopic mass dimensions can be misleading after serum β-hCG levels have declined to <15 mIU/mL. Brown and colleagues (1991) described persistent masses to be resolving hematomas rather than persistent trophoblastic tissue. For this reason, posttherapy sonography is reserved for suspected complications such as tubal rupture. Approximate time to resolution for all women averages 36 days, but in some, treatment requires as long as 109 days (Lipscomb, 1998).

After successful medical therapy with MTX, pregnancy is delayed for at least 3 months, as this drug may persist in human tissues for months after a single dose (Hackmon, 2011). Although data are very limited, conception before this waiting period appears reassuring. In one study, 45 women who conceived <6 months after MTX had similar pregnancy outcomes compared with 80 women who conceived >6 months after MTX (Svirsky, 2009). In the long term, ovarian reserve does

not appear diminished with MTX use for this indication (Hill, 2014; Ohannessian, 2014).

Surgical Management

For surgical removal of an ectopic pregnancy, two procedures—salpingectomy or salpingostomy—are options. With salpingectomy, the entire fallopian tube is removed, and this is suitable for ruptured or unruptured tubes. With rare exception, the entire conceptus is removed with the fallopian tube. Thus, cases of persistent trophoblastic tissue with salpingectomy are uncommon.

In contrast, salpingostomy is typically used to remove a small, unruptured pregnancy yet preserve the fallopian tube. For this, a 15-mm linear incision is made on the antimesenteric border of the fallopian tube over the pregnancy. The products usually will extrude from the incision and can be carefully removed (Chap. 44, p. 1028). Main risks include postoperative bleeding from the tubal incision or trophoblast left within the tube that later causes tubal rupture.

For salpingostomy, a suitable candidate is one who is hemodynamically stable and desires fertility preservation. This applies especially if the other fallopian tube is absent or damaged. In addition to tubal attributes, serum β-hCG levels may influence patient selection. One retrospective study found that ectopic resolution rates were lower following salpingostomy in women in whom the initial serum β-hCG level was >8000 mIU/mL (Milad, 1998). Supportive evidence for this comes from Natale and coworkers (2003), who reported that serum β-hCG levels >6000 mIU/mL have a high risk of implantation into the tubal muscularis. Such implantation would hinder complete trophoblast removal during surgery.

Although salpingectomy achieves a higher initial surgical resolution rate, one concern was that later fertility rates would be lower than those following salpingostomy. In response, two randomized trials have compared laparoscopic outcomes between these two procedures in women with a normal contralateral fallopian tube. The European Surgery in Ectopic Pregnancy (ESEP) study randomized 231 women to salpingectomy and 215 to salpingostomy. After surgery and in subsequent pregnancies, the cumulative rates of ongoing pregnancy by natural conception did not differ significantly between groups–56 versus 61 percent, respectively (Mol, 2014). Again, in the DEMETER trial, the subsequent 2-year rate for achieving an IUP did not significantly differ between groups–64 versus 70 percent, respectively (Fernandez, 2013). One large cohort study had similar findings (Li, 2015b). Thus, if the contralateral fallopian tube appears normal, salpingectomy is a reasonable treatment option that avoids the 5- to 8-percent complication rate caused by persistent or recurrent ectopic pregnancy in the same tube (Rulin, 1995). For women with an abnormal-appearing contralateral tube, salpingostomy is a conservative option for fertility preservation.

Regarding abdominal entry for ectopic surgery, several studies have compared laparotomy with laparoscopy for completion of either salpingectomy or salpingostomy (Murphy, 1992; Lundorff, 1991; Vermesh, 1989). For either tubal surgery, both entry options yielded equivalent ectopic resolution rates and subsequent IUP rates. Moreover, in studies of salpingostomy specifically, tubal patency rates were similar, but fewer adnexal adhesions formed following laparoscopy. However, in one systematic review, laparoscopic salpingostomy had a 13-percent rate of persistent trophoblastic disease compared with a rate of 3 percent with laparotomic salpingostomy (Mol, 2008).

In sum, laparoscopy is the preferred surgical treatment for ectopic pregnancy unless a woman is hemodynamically unstable. As experience has accrued, cases previously managed by laparotomy—for example, ruptured tubal pregnancies with hemoperitoneum—can safely be managed laparoscopically by those with suitable expertise (Cohen, 2013; Sagiv, 2001). That said, the lowered venous return and cardiac output associated with the pneumoperitoneum of laparoscopy must be factored into the decision to select minimally invasive surgery for a hypovolemic woman.

Before surgery, future fertility desires are discussed. In women desiring permanent sterilization, the unaffected tube can be removed concurrently with salpingectomy for the affected fallopian tube.

Medical versus Surgical Therapy

Multidose MTX treatment and laparoscopic salpingostomy have been compared in one randomized trial of 100 patients. The authors found no differences for rates of tubal preservation, primary treatment success, and subsequent fertility (Dias Pereira, 1999; Hajenius, 1997).

For single-dose MTX, its efficacy compared with laparoscopic salpingostomy shows conflicting results. In one randomized trial, single-dose MTX was less successful in pregnancy resolution, whereas in the other, single-dose MTX was equally effective (Saraj, 1998; Sowter, 2001). Krag Moeller and associates (2009) reported during a median surveillance period of 8.6 years that ectopic-resolution success rates and cumulative spontaneous IUP rates were not significantly different between those managed by laparoscopic salpingostomy and those treated with single-dose MTX.

Salpingectomy effectively removes the entire conceptus and yields high resolution rates. It thus outperforms MTX in this regard. Yet, when future fertility and ectopic pregnancy recurrence rates are analyzed, both salpingectomy and MTX therapy show comparable results (de Bennetot, 2012; Irani, 2017). In another study, surgery, MTX, or expectant management all yielded statistically similar subsequent spontaneous IUP rates (Demirdag, 2017).

In sum, medical or surgical management offer similar outcomes in women who are hemodynamically stable, have serum β-hCG concentrations <5000 mIU/mL, and have a small pregnancy with no fetal cardiac activity. Despite lower success rates with medical therapy for women with larger tubal size, higher serum β-hCG levels, and fetal cardiac activity, medical management can be offered to the motivated woman who understands the risks of emergency surgery in the event of treatment failure.

Expectant Management

In anticipation that a tubal ectopic pregnancy will spontaneously resolve, close observation is reasonable in select women without pain or significant bleeding. A commitment to surveillance visits and relative proximity to an emergency department are other safeguards. Importantly, this differs from expectant management of a PUL during its evaluation.

Consensus guidelines are difficult to formulate from available small studies, which have markedly disparate inclusion criteria. Despite this, predictive factors for success include a low initial serum β-hCG concentration, a significant drop in levels over 48 hours, and a sonographic inhomogeneous mass rather than a tubal halo or other gestational structure. For example, initial values <175 mIU/mL predict spontaneous resolution in 88 to 96 percent of attempts (Elson, 2004; Kirk, 2011). Initial values <1000 mIU/mL have success rates ranging from 71 to 92 percent (Jurkovic, 2017; Mavrelos, 2013; Silva, 2015).

Regarding subsequent fertility, Shalev and associates (1995) found no difference in rates of ipsilateral tubal patency, recurrent ectopic pregnancy, or 1-year fertility with either success or failed expectant management. In another study, expectant management and salpingectomy had similar rates of recurrent ectopic or of subsequent spontaneous IUP (Helmy, 2007).

Resolution time with expectant management approximates 3 weeks, and β-hCG concentrations are followed to undetectable levels (Mavrelos, 2015). Close monitoring is warranted during this time because the risk of tubal rupture persists despite low or declining serum β-hCG levels (Fu, 2007). Moreover, an argument could be made that the minimal side effects of MTX may make it preferable to expectant-care disadvantages. These include a potentially prolonged surveillance, patient anxiety, and tubal rupture risk.

Persistent Ectopic Pregnancy

Incomplete eradication of trophoblastic tissue and its continued growth causes tubal rupture in 3 to 20 percent of women following conservative surgical or medical treatment of ectopic pregnancy (Graczykowski, 1999). Rarely, surgically dislodged trophoblast can also secondarily implant on abdominal surfaces and bleed. Thus, abdominal pain following ectopic pregnancy treatment prompts immediate suspicion for persistent trophoblast proliferation.

Following salpingostomy, persistent ectopic pregnancy can complicate very early pregnancies (Nathorst-Böös, 2004). And, as discussed earlier, higher initial β-hCG levels that may reflect greater tubal muscularis invasion are another predictor (Lund, 2002). To obviate persistent trophoblast, Graczykowski and associates (1997) administered a prophylactic MTX dose of 1 mg/m^2 BSA postoperatively. This reduced the incidence of persistent ectopic pregnancy and shortened the length of surveillance. But again, this is balanced against MTX side effects. Our practice is to watch hormone levels rather than to use prophylactic MTX.

The optimal monitoring schedule to identify persistent ectopic pregnancy after surgical therapy has not been determined. Protocols describe serum β-hCG level monitoring from every 3 days to every 2 weeks. Spandorfer and associates (1997) estimated the risk of persistent ectopic pregnancy based on serum β-hCG levels done on the first postoperative day after salpingostomy. They observed that if serum β-hCG levels fell by >50 percent compared with presurgical values, there were no treatment failures within the first 9 days, and thus repeat serum β-hCG determinations 1 week after surgery were appropriate. Conversely, if serum levels fell by <50 percent, there was a 3.5-fold greater risk of failure within the first week, thus necessitating earlier postoperative evaluation. Currently, standard therapy for persistent ectopic pregnancy in clinically stable women is single-dose MTX with 50 mg/m^2 BSA.

CESAREAN SCAR PREGNANCY

Among women with a prior cesarean delivery, implantation within a prior cesarean hysterotomy scar develops in approximately 1 in 2000 pregnancies (Seow, 2004). Similar to patients with ectopic pregnancy in other locations, affected women may have vaginal bleeding or abdominal pain, but up to 33 percent are asymptomatic (Rotas, 2006).

Cesarean scar pregnancies (CSPs) are usually diagnosed in the first trimester, and transvaginal sonography is essential (Fig. 7-9). Diagnostic criteria include: (1) an empty uterine

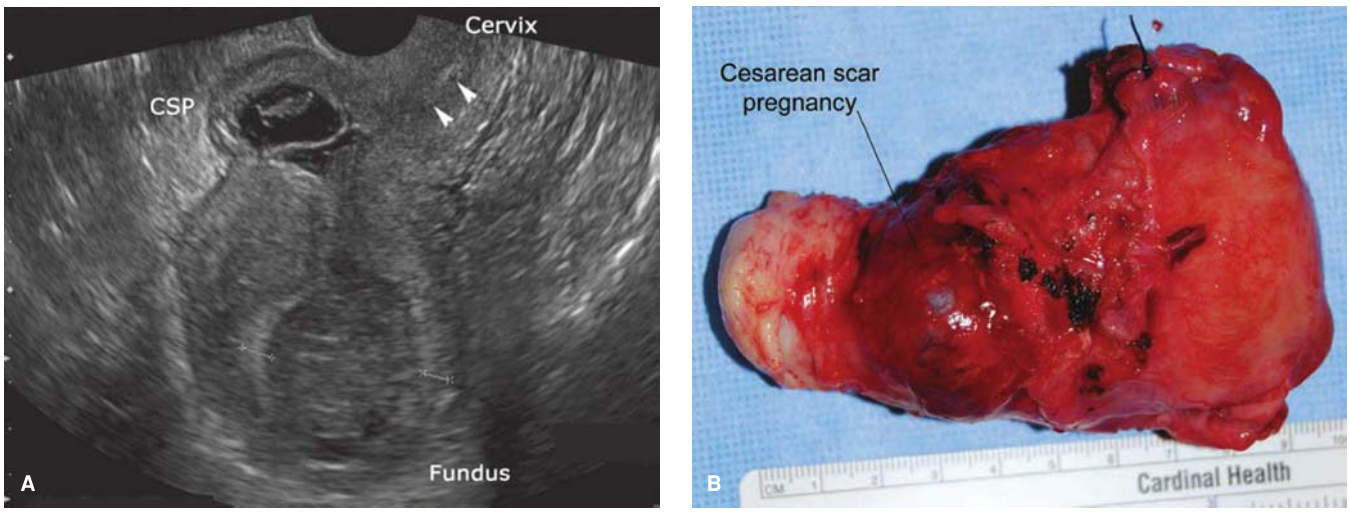

FIGURE 7-9 Cesarean scar pregnancy. **A.** Transvaginal sonogram of a uterus with a cesarean scar pregnancy (*CSP*) in a sagittal plane. The diagnosis is suggested by sonographic criteria indicative of CSP. First, the uterine cavity contains only heterogeneous echoes suggestive of clot. The endometrium is measured by calipers here. An empty cervical canal is identified by a bright hyperechoic endocervical stripe (*white arrowheads*). Last, an intrauterine mass is seen in the anterior part of the uterine isthmus. **B.** Hysterectomy specimen containing a cesarean scar pregnancy. The fundus lies to the right. (Reproduced with permission from Dr. Sunil Balgobin.)

cavity and empty endocervical canal, (2) placenta or gestational sac embedded in the hysterotomy scar niche, (3) a thin myometrial mantle between the gestational sac and bladder, and (4) a prominent vascular pattern at the scar (Timor-Tritsch, 2012). Mimics include a spontaneous expelling abortus or a cervicoisthmic implantation. To help differentiate these, inability to displace or propel the gestational sac from its position using gentle pressure applied by the endovaginal probe suggests implantation (Jurkovic, 2003; Moschos, 2008a).

For management, insights into the pathogenesis of CSPs are providing new options. Namely, growing evidence suggests that some of these pregnancies will not behave as a typical ectopic pregnancy, and thus rates of rupture and bleeding are lower. Instead, CSPs are thought by some to be a precursor of morbidly adherent placenta (Rac, 2016; Timor-Tritsch, 2014). As such, a significant percentage of affected pregnancies will progress to a viable-aged neonate, albeit with the complications associated with placenta accreta (Cali, 2018; Timor-Tritsch, 2015). These include preterm delivery, hemorrhage, and hysterectomy.

With expectant care of CSPs, one systematic review of 69 patients found that uterine rupture or dehiscence complicated 10 percent of all cases (Cali, 2018). During the first or second trimester, hysterectomy was performed in 15 percent. For the 40 patients progressing to the third trimester, 17 had placenta percreta, 23 patients underwent hysterectomy, and two patients had uterine rupture or dehiscence. For all trimesters, 60 percent of cases ultimately underwent hysterectomy. More reassuringly, in early pregnancies without cardiac activity, 70 percent had uncomplicated miscarriage, whereas 30 percent required surgical or medical intervention. None required hysterectomy. Thus, women accepting expectant care are ideally well counseled on these potential obstetric complications.

Patients may prefer to avoid these risks and seek pregnancy termination. From one literature review, the most successful interventions include: (1) laparoscopic uterine isthmic resection; (2) transvaginal resection of the isthmus through an anterior colpotomy, created similarly to anterior entry during vaginal hysterectomy; (3) uterine artery embolization (UAE) followed by D & C with or without hysteroscopy; and (4) hysteroscopic resection (Birch Petersen, 2016; Wang, 2014). In some instances, hysterectomy is required or may be elected in those not desiring future fertility (Hudeck, 2014; Sadeghi, 2010).

Medical management is an option for those hoping to avoid surgery. However, compared with surgery, pregnancy resolution rates are more varied. In one systematic review, local MTX injection alone provided a success rate of approximately 60 percent, and systemic plus local MTX injection raised the rate to nearly 80 percent (Maheaux-Lacroix, 2017). More recently, a novel double-balloon catheter, in which the balloons lie in tandem, has been used in a few case series (Monteagudo, 2018; Timor-Tritsch, 2016). The cephalad balloon tightly fills the endometrial cavity to prevent device expulsion, whereas the lower balloon interrupts the CSP via mechanical pressure and tamponades any potential bleeding.

Subsequent normal pregnancies can follow CSP, but recurrence rates are high. In one recent series of ten subsequent pregnancies in women with a prior CSP, four were recurrent CSPs (Grechukhina, 2018).

INTERSTITIAL PREGNANCY

This ectopic pregnancy implants within the proximal tubal segment that lies within the muscular uterine wall. Swelling lateral to the insertion of the round ligament is the characteristic anatomic finding (Fig. 7-10). Incorrectly, these are sometimes called *cornual pregnancies*, but this term correctly describes conceptions that develop in the horns of uteri with müllerian anomalies (Moawad, 2010). Cornual pregnancies are described in Chapter 19 (p. 422). In the past, interstitial conceptions classically ruptured later than pregnancies found in other tubal portions. This is attributed to the greater distensibility of the myometrium covering the fallopian tube's interstitial segment. Risk factors are similar to those for other ectopic locations, although prior ipsilateral salpingectomy is a specific risk factor for interstitial pregnancy (Lau, 1999).

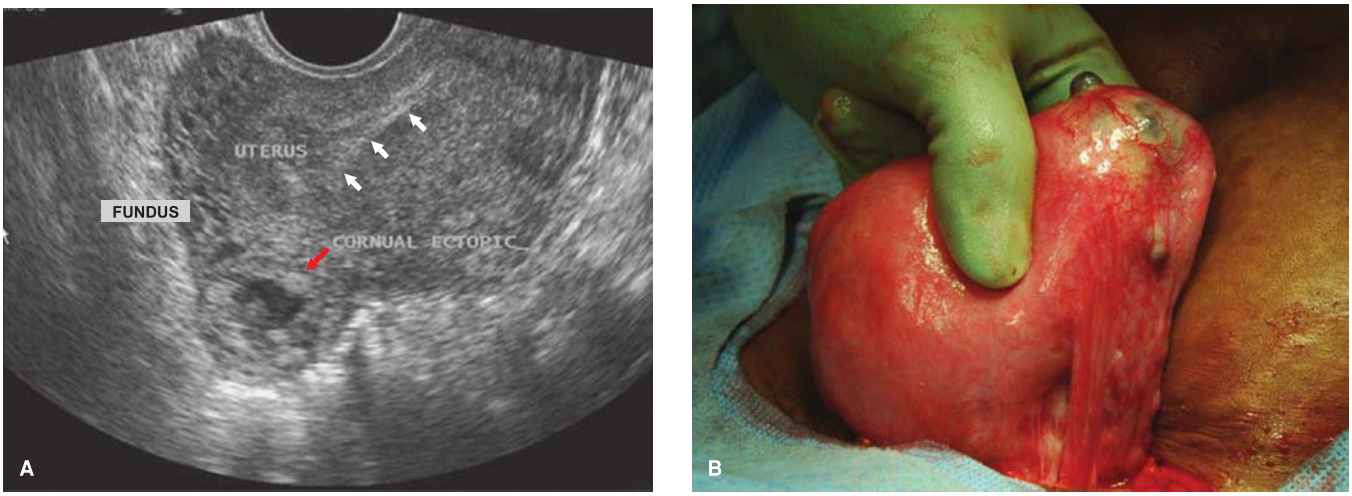

FIGURE 7-10 Interstitial pregnancy. **A.** Transvaginal sonogram, parasagittal view showing an empty uterine cavity (*white arrows*) and a mass lateral to the uterine fundus (*red arrow*). (Reproduced with permission from Dr. Elysia Moschos.) **B.** Interstitial pregnancy prior to resection. (Reproduced with permission from Dr. Mario Castellanos.)

Distinct from interstitial pregnancy, the term a*ngular pregnancy* describes intrauterine implantation in one of the lateral angles of the uterus and medial to the uterotubal junction and round ligament. This distinction is important because angular pregnancies can sometimes be carried to term but have a greater risk of abnormal placentation or uterine rupture late in pregnancy (Arleo, 2014; Jansen, 1981).

Diagnostically, symptoms of interstitial pregnancy mirror those of pregnancies at other tubal sites. Sonographically, criteria include a gestational sac that lies outside the endometrial cavity and >1 cm away from the endometrium. The sac is intramyometrial but is covered only by a <5-mm muscular mantle. Last, an echogenic line, known as the *interstitial line sign*, may be seen extending between the gestational sac and endometrial cavity and most likely represents the interstitial portion of the fallopian tube (Ackerman, 1993; Timor-Tritsch, 1992). Improved imaging from 3-dimensional sonography may help differentiate angular and interstitial gestations (Tanaka, 2014).

For interstitial pregnancies, surgical management involves cornual resection or evacuation by laparotomy or laparoscopy (Chap. 43, p. 947). Rather than conservative management with MTX, surgery is often preferred because of the proximity of these pregnancies to both the uterine and ovarian arteries. Hemorrhage with rupture can be severe and is associated with mortality rates as high as 2.5 percent (Tulandi, 2004). Also, although the risk of recurrence in a subsequent pregnancy is rare, cornuectomy has the lowest associated rates (Egger, 2017).

If elected, MTX can be administered in several routes. Jermy and colleagues (2004) reported a 94-percent success with systemic IM MTX using a dose of 50 mg/m^2 BSA (see Table 7-3). Others employ a traditional multidose MTX regimen (Hiersch, 2014). Direct MTX injection into the gestational sac also offers comparable success (Framarino-dei-Malatesta, 2014). Last, uterine artery MTX infusion and then embolization—"chemoembolization"—combined with systemic methotrexate has shown promise (Krissi, 2014).

Following either medical or conservative surgical management, the risk of uterine rupture with subsequent pregnancies is unclear. Several small case series describe no uterine rupture in women delivering vaginally (Hoyos, 2019; Ng, 2009; Tulandi, 2004). In our and others' experiences, rupture rates are higher (Liao, 2017; Kim, 2017; Svenningsen, 2019). Thus, careful observation of these women during pregnancy, along with consideration of elective cesarean delivery, is reasonable.

CERVICAL PREGNANCY

This ectopic pregnancy location is rare, and risk factors are ART and prior D & C (Ginsburg, 1994; Hung, 1996). For cervical pregnancy confirmation, cervical glands must be found opposite the placental attachment site. Also, at least a portion of the placenta is located below the entrance of the uterine vessels or below the peritoneal reflection on the anterior and posterior uterine surface (Rubin, 1911). Sonographic criteria are shown in Figure 7-11.

For most hemodynamically stable women with a first-trimester cervical pregnancy, nonsurgical management with either single- or multidose systemic MTX can be administered (see Table 7-3) (Murji, 2015). Alternatively, 50 mg of MTX can be injected directly into the gestational sac (Jeng, 2007; Yamaguchi, 2017). Others describe MTX chemoembolization, as just described for interstitial pregnancy (Xiaolin, 2010). Higher risk of systemic MTX treatment failure is noted in those with a gestational age >9 weeks, β-hCG levels >10,000 IU/L, and fetal cardiac activity (Hung, 1996). For this reason, many induce fetal death with injection of potassium chloride (KCL)

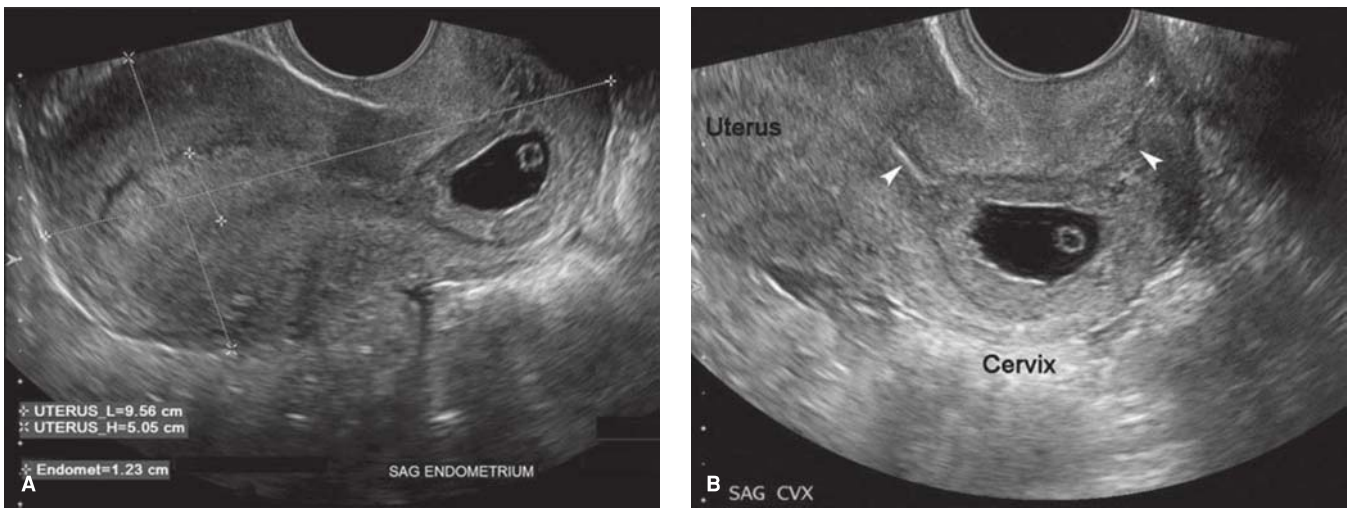

FIGURE 7-11 Cervical pregnancy. **A.** Transvaginal sonography, sagittal view of a uterus containing a cervical pregnancy. Calipers mark the uterine length and depth and endometrial thickness. Sonographic findings with cervical pregnancy may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix; (3) absent intrauterine gestational tissue (*inner calipers*); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. An absent "sliding sign" helps differentiate a cervical pregnancy from the transcervical passage of a miscarriage. With the maneuver, gentle pressure is applied to the cervix by the vaginal probe, and the gestation sac of an abortus will move or slide against the endocervical canal. This will not be seen in an implanted cervical pregnancy. **B.** In this sonogram of the same cervix, a portion of the endocervical canal (*white arrowheads*) is seen on either side of the gestational sac. (Reproduced with permission from Dr. Angela R. Seasley.)

into the fetus or gestational sac (Jeng, 2007; Verma, 2009). One option is 1 mL of 2 mEq/mL KCL. UAE may be valuable to treat bleeding complications.

Although conservative management is feasible for many women with cervical pregnancies, surgical intervention also may be selected. Procedures include suction evacuation or hysterectomy. Moreover, in those with advanced gestations or with bleeding uncontrolled by conservative methods, hysterectomy is typically required. Prior to either procedure, UAE may be considered to limit intra- and postoperative bleeding (Hu, 2016; Trambert, 2005).

If suction evacuation is selected, dilatation is not required and incites brisk bleeding, as does sharp curettage. Aside from UAE, intraoperative hemorrhage can also be lessened by intracervical vasopressin injection or by a cerclage placed at the internal cervical os to compress feeding vessels (Ishikawa, 2016; Trojano, 2009). Also, cervical branches of the uterine artery can effectively be ligated with vaginal placement of hemostatic cervical sutures on the lateral aspects of the cervix at 3 and 9 o'clock (Bianchi, 2011). Following suctioning, in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon or the double-balloon catheter described earlier can be inflated to effect hemostasis and to monitor bloody drainage (p. 172) (Fylstra, 2014). The balloon remains inflated for 24 hours and is gradually deflated. In addition, UAE may be considered.

OVARIAN PREGNANCY

Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These include: (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the ovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically in the placental tissue (Spiegelberg, 1878). Of risk factors, IVF and IUD use are prominent (Zhu, 2014).

In one review of 100 cases, nearly a third of women presented with hemodynamic instability because of rupture (Ko, 2012). In unruptured cases, the classic sonographic description is that of a cyst with a wide echogenic outer ring on or within the ovary. This may mimic a corpus luteum cyst (Comstock, 2005).

These pregnancies are managed surgically. With smaller ectopic pregnancies, ovarian wedging can be considered (Raziel, 2004). For larger or significantly ruptured lesions, oophorectomy is often required.

HETEROTOPIC PREGNANCY

A uterine pregnancy in conjunction with an extrauterine pregnancy is termed a *heterotopic pregnancy*. The natural incidence of these heterotopic pregnancies approximates 1 per 30,000 pregnancies (Reece, 1983). ART is one risk factor, and the heterotopic pregnancy rate approximates 9 per 10,000 in ART-treated women (Perkins, 2015). MTX is contraindicated due to the detrimental effects on the normal pregnancy (p. 169). Thus, most tubal pregnancies are excised surgically.

OTHER ECTOPIC PREGNANCY SITES

Abdominal pregnancy forms from implantation in the peritoneal cavity. This may result from primary implantation or may develop following tubal abortion and subsequent peritoneal implantation. Other less expected sites have been described in case reports and include the omentum, liver, and retroperitoneum, among others (Brouard, 2015; Liang, 2014; Watrowski, 2015).

A tubal pregnancy implanted toward the mesosalpinx may rupture into a space formed between the leaves of the broad ligament to become an *intraligamentous* or *broad ligament pregnancy*. Rents in prior cesarean scars serve as another conduit into this space (Rudra, 2013).

Intramural uterine pregnancies form at sites other than a cesarean scar, and risk factors are prior uterine surgeries, ART, or adenomyosis (Kirk, 2013; Memtsa, 2013). Clinically, these pregnancies can mimic invasive gestational trophoblastic tissue.

Rarely, ectopic pregnancies have been reported in women with prior hysterectomy (Fylstra, 2010). Presumably, a vaginal cuff fistula, a prolapsed fallopian tube, or a cervical stump allows sperm to access an ovulated ovum. For all these unique locations, surgical excision is generally required.

PATHOPHYSIOLOGY

The endometrium is the source of most abnormal reproductive tract bleeding. It consists of two distinct zones, the functionalis layer and the basalis layer (Fig. 8-1). The basalis layer lies in direct contact with the myometrium and beneath the functionalis layer. The basalis serves as a reservoir for regeneration of the functionalis layer following menses. In contrast, the functionalis layer lines the uterine cavity and undergoes dramatic change throughout the menstrual cycle. It ultimately sloughs during menstruation. Histologically, the functionalis has a surface epithelium and underlying subepithelial capillary plexus. Beneath these are stroma, glands, and interspersed leukocytes (Fig. 33-1, p. 701).

Blood reaches the uterus via the uterine and ovarian arteries (see Fig. 8-1). From these, the arcuate arteries arise to supply the myometrium. These in turn branch into the radial arteries, which extend toward the endometrium at right angles from the arcuate arteries. At the endometrium-myometrium junction, the radial arteries bifurcate to create the basal and spiral arteries. The basal arteries serve the basalis layer of the endometrium and are relatively insensitive to hormonal changes. The spiral arteries stretch to supply the functionalis layer and end in a subepithelial capillary plexus.

In human menstruation, progesterone plays a critical role. Two progesterone receptors (PR) are found in the endometrium, PRA and PRB. In the secretory phase, PRB levels decline in the stromal and glandular epithelial cells of the functionalis layer. However, PRA expression in this layer persists in the stromal cells, which thus remain responsive to progesterone and to its withdrawal (Maybin, 2015).

In the absence of pregnancy, the corpus luteum regresses and curtails progesterone production. Progesterone acts as an antiinflammatory agent, and thus its withdrawal raises cytokine levels in the endometrium. Elevated concentrations of cytokines prompt an influx of leukocytes, which release lytic enzymes. These matrix metalloproteinases break down the stroma and vascular architecture of the functionalis layer (Critchley, 2011). Subsequent bleeding and sloughing of this layer constitute menstruation (Jabbour, 2006). Concurrently, endometrial levels of tissue factor and plasminogen activator inhibitor-1 drop with progesterone withdrawal. These two proteins foster hemostasis during the luteal phase, but their decline promotes an environment conducive to bleeding and fibrinolysis (Lockwood, 2011). Last, progesterone withdrawal raises concentrations of cyclooxygenase-2, a necessary enzyme in prostaglandin PG synthesis. As a result, levels of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) rise and cause intense spiral arteriole constriction. Explanations differ as to whether this vasoconstriction produces a hypoxia needed to prompt endometrial sloughing or whether it serves to minimizes menstrual blood loss (Maybin, 2015; Schatz, 2016).

Hemostasis and cessation of menstruation are dependent on the endometrial coagulation system. Initially, platelets aggregate and are activated in response to endothelial injury. This occurs by either platelet glycoprotein interaction with von Willebrand factor or tissue factor generation of thrombin. Subsequently, fibrin is formed through the coagulation cascade to help form a stable clot to seal bleeding vessels. In addition, the remaining endometrial arterioles constrict to limit further bleeding (Ferenczy, 2003). During menses, augmented endometrial glucocorticoid production also helps to control blood loss by dampening the inflammatory response.

Dysregulation in any of the above events can lead to abnormal menstruation and greater blood loss.

DEFINITIONS

Women normally menstruate every 28 ± 7 days. The average duration is 5 days, and menstrual blood loss volume does not normally exceed 80 mL. Variations in any of these norms constitute *abnormal uterine bleeding (AUB)*, which may be acute or chronic. Acute AUB is defined as bleeding sufficiently heavy to require immediate intervention to prevent ongoing losses. Chronic AUB is defined as bleeding that has been present

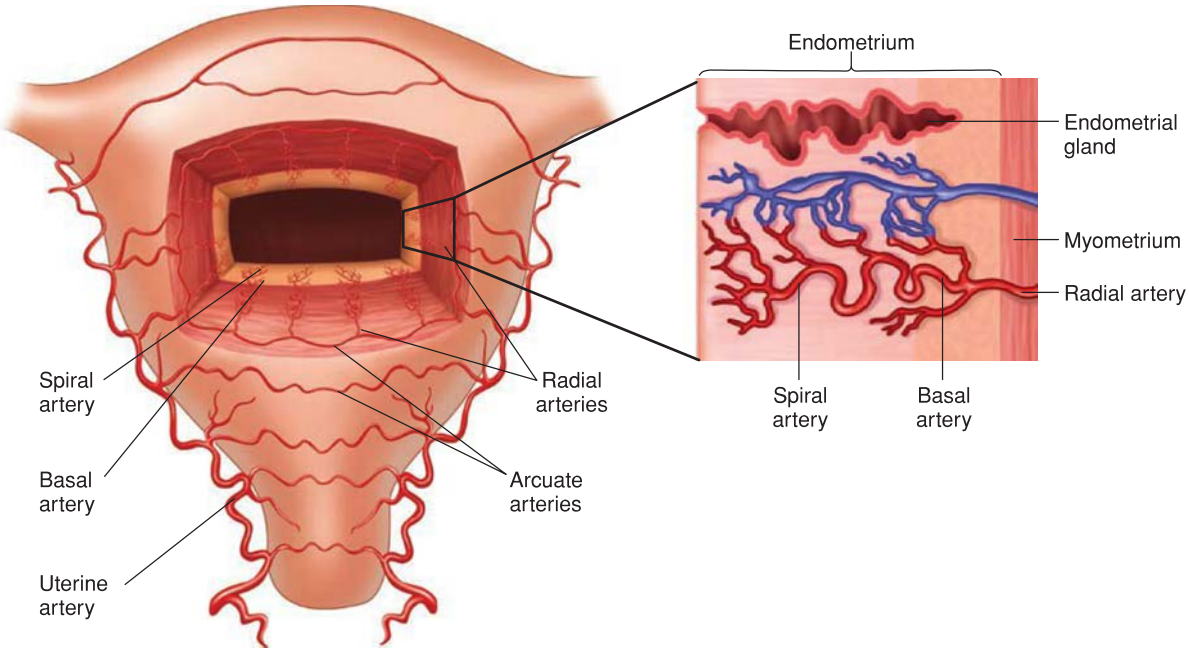

FIGURE 8-1 Drawing of uterine blood supply and endometrial anatomy.

during most of the prior 6 months. Because AUB can display several patterns, the descriptive terms listed next help standardize nomenclature (Munro, 2018).

Menses are ideally categorized by four qualities—volume, duration, frequency, and regularity (Table 8-1). *Heavy menstrual bleeding (HMB)*, which was formerly called menorrhagia, describes menstruation with excessive flow. Objectively, this has been defined as >80 mL of blood loss per menstrual period. Second, the duration of menses may vary, with *prolonged bleeding* lasting >8 days per menstrual period. In some cases, women may complain of both, which is described as *heavy, prolonged menstrual bleeding*. A third quality is frequency, which reflects the number of days between menses. *Frequent bleeding* describes menses with <24 days intervening. *Infrequent bleeding,* previously called oligomenorrhea, is defined by menses with >38 days intervening. Absence of menstrual bleeding in a 90-day period is defined as *amenorrhea*. Last, regularity describes the variability of cycle lengths. If cycle lengths vary from cycle to cycle by ≥10 days, they are considered irregular. As an example, one cycle length is 28 days, but the next is 60 days.

Previously, "dysfunctional uterine bleeding (DUB)" was often used to describe abnormal uterine bleeding without a clear underlying pathology. This term has now been abandoned in favor of describing the specific disorders (Fraser, 2011a).

Specific terms also describe nonmenstrual bleeding. *Intermenstrual bleeding* defines bleeding, usually brief, that occurs between fairly normal menses. This term replaces metrorrhagia. Intermenstrual bleeding may be further defined by clinical context. For example, intermenstrual bleeding prompted by vaginal intercourse is called *postcoital bleeding*. The terms *pre-* and *postmenstrual spotting* are self-explained. *Breakthrough bleeding* and *unscheduled bleeding* are terms associated with hormone administration. Another term, *withdrawal bleeding*, refers to the predictable bleeding that results from an abrupt decline in progesterone levels. Last, women may experience bleeding outside the reproductive years. *Precocious menstruation* is initiation of menses in childhood and described in Chapter 15 (p. 329). *Postmenopausal bleeding* is included in this chapter.

Although HMB is defined as menstrual blood loss >80 mL, evaluation can proceed based solely on a patient's description of

TABLE 8-1. Recommended Terminology for Normal and Abnormal Menses

Quality	Normal	Abnormal		Prior Terms
Volume	5–80 mL	Light (<5 mL)	Heavy (>80 mL)	hypomenorrhea, menorrhagia
Duration	≤8 d	Prolonged (>8 d)		hypomenorrhea, menorrhagia
Frequency: days between menses				
	24–38 d	Frequent (<24 d)	Infrequent (>38 d) Amenorrhea (>90 d)	polymenorrhea, oligomenorrhea
Regularity: numbers of days by which cycle lengths vary				
	≤7–9 d	Irregular ≥10 d		

flow that suggests HMB. Of objective methods, Hallberg and associates (1966) first described a technique to extract hemoglobin from sanitary napkins using sodium hydroxide. Hemoglobin is then converted to hematin and measured spectrophotometrically. This alkaline hematin technique has since been modified and revalidated for use with modern sanitary napkins that contain superabsorbent polymer granules (Magnay, 2010). Although used in research, this precise approach has obvious constraints in a routine clinical setting.

Other tools used to estimate menstrual blood loss include hemoglobin and hematocrit evaluation. Hemoglobin concentrations below 12 g/dL raise the chance of identifying HMB. A normal level, however, does not exclude HMB, as many women with clinically significant bleeding have normal values.

Another method involves estimating the number and type of pads or tampons used by a woman during menses. Warner and colleagues (2004) found positive correlations between objective HMB and passing clots more than 1 inch in diameter and changing pads more frequently than every 3 hours. Attempts to standardize this type of evaluation have led to the pictorial blood assessment chart (PBAC) (Fig. 8-2). Using a scoring sheet, patients are asked to record daily the number of sanitary products that are lightly, moderately, or completely saturated. Scores are assigned as follows: 1 point for each lightly stained tampon, 5 if moderately saturated, and 10 if completely soaked. Pads are similarly given ascending scores of 1, 5, and 20, respectively. Presence of small, 2-mm-diameter clots score 1 point, whereas 3-mm clots score 5. Points are then tallied for each day. Totals >100 points per menstrual cycle correlate with >80 mL objective blood loss (Higham, 1990).

As another option, a menstrual cup may offer a more direct method of measure. Seated in the vagina similar to a diaphragm, these cups allow trapping and collection of menstrual blood. Several times during the day, a woman can remove, empty, wash, and replace. Differing sizes and stiffness accommodate parous or nulliparous anatomy. Disposable brands are also available.

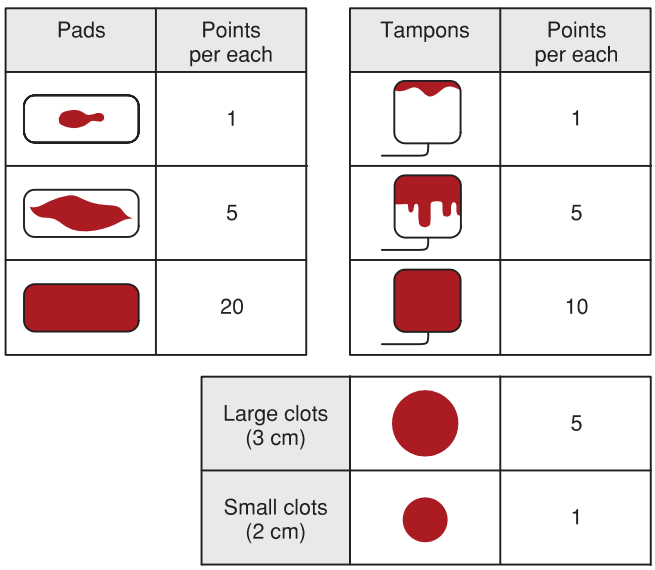

FIGURE 8-2 Scoring for the pictorial bleeding assessment chart. Patients are counseled to evaluate the degree of saturation for each sanitary product used during menstruation. Total points are tallied for each menses. Point totals >100 per menses indicate heavy menstrual bleeding.

Menstrual calendars are another option to evaluate AUB and its patterns. With this, patients are asked to record dates and blood flow quantity throughout the month. These calendars can be used to aid diagnosis and to document improvement during medical treatment. Smartphone applications, or "apps," are similarly available to chart menstrual timing and flow (Moglia, 2016). Clue and iPeriod apps allow daily menstrual flow charting and comments. The Me-Period Flow Assessment specifically collects PBAC data.

ETIOLOGY

Depending on whether subjective self-reporting or objective blood loss measurement is used, the true population rates of AUB can vary. Data may also differ depending on the definitions used for AUB. Commonly cited rates range from 10 to 30 percent (Liu, 2007; Matteson, 2013).

Age and reproductive status most greatly influence AUB incidence, and these factors can help prioritize potential etiologies. Prior to menarche, bleeding is investigated as an abnormal finding. In children, the vagina, rather than the uterus, is more frequently involved. True uterine bleeding usually results from increased exposure to endogenous or exogenous estrogen. Bleeding in this age group is discussed in Chapter 15 (p. 329).

In adolescence, AUB results from anovulation and coagulation defects at disproportionately higher rates compared with older reproductive-aged women (Ahuja, 2010). In contrast, benign or malignant neoplastic growths are less frequent. Pregnancy, sexually transmitted diseases (STDs), and sexual abuse are also possibilities in this population.

Following adolescence, the hypothalamic-pituitary-ovarian (HPO) axis matures, and anovulatory uterine bleeding is encountered less often. With greater sexual activity, rates of bleeding related to pregnancy and STDs rise. The incidences of bleeding from leiomyomas, adenomyosis, and endometrial polyps also increase with age.

During the perimenopause, as with perimenarchal girls, anovulatory uterine bleeding from HPO axis dysfunction is a more frequent finding (Chap. 22, p. 476). In contrast, the incidences of bleeding related to pregnancy and STDs decline. With aging, risks of benign and malignant neoplastic growth rise.

After menopause, bleeding typically can be traced to a benign origin such as endometrial or vaginal atrophy or polyps. Even so, malignant neoplasms, especially endometrial carcinoma, are found more often in this age group. Less commonly, estrogen-producing ovarian carcinoma may cause endometrial hyperplasia and uterine bleeding. Similarly, ulcerative vulvar, vaginal, or cervical neoplasms can be sources. Rarely, serosanguinous discharge from a fallopian tube cancer may appear as uterine bleeding. Thus, bleeding in this demographic usually prompts evaluation to exclude these cancers.

The causes of reproductive tract bleeding are numerous (Table 8-2). To organize the main causes of AUB, the International Federation of Gynecology and Obstetrics (FIGO) created a classification system using the acronym

TABLE 8-2. Reproductive Tract Bleeding

Uterine Bleeding

PREGNANCY: Normal implantation, abortion, ectopic, mole

STRUCTURAL

Polyps: endometrial, endocervical

Adenomyosis

Leiomyomas

Malignancy:
Preinvasive: CIN, EIN
Cancer: cervical, endometrial, sarcoma

NONSTRUCTURAL

Coagulopathy: inherited, liver failure, immunologic

Ovulatory
Adolescent HPO immaturity
Perimenopausal follicle aging
Premature ovarian failure
Androgen excess: PCOS, CAH, Cushing syndrome/disease
Hypothyroidism
Obesity
Hyperprolactinemia: pituitary or hypothalamic disorder
HPO dysregulation: stress, anorexia, extreme exercise

Endometrial: Atrophy, intrinsic abnormality, endometrial hyperplasia, chronic endometritis

Iatrogenic:
Intrauterine device
Medications: sex steroid agent or SERM, anticoagulants, valproate, hyperprolactinemia-inducing agent

Not otherwise specified:
Infection: PID, cervicitis, TB, postabortal/postpartum
Arteriovenous malformation
Partial sequestration of menses: isthmocele, Asherman syndrome

Other Lower Genital Tract Bleeding

Malignancy: vaginal, vulvar, fallopian tube, ovarian hormone-producing

Traumatic: vulvar or vaginal trauma, foreign body

Partial outlet obstruction: transverse or longitudinal septum

Other: postsurgical granulation tissue, prolapsed fallopian tube, vaginal adenosis

CAH = congenital adrenal hyperplasia; CIN = cervical intraepithelial neoplasia; EIN = endometrial intraepithelial neoplasia; HPO = hypothalamic-pituitary-ovarian axis; PID = pelvic inflammatory disease; PCOS = polycystic ovarian syndrome; SERM = selective estrogen-receptor modulator; TB = tuberculosis.

PALM-COEIN (Munro, 2011, 2018). Letters are grouped by structural and nonstructural causes of AUB, respectively, and reflect the following categories: polyp, adenomyosis, leiomyoma, malignancy and hyperplasia, coagulopathy, ovulatory disorders, endometrial dysfunction, iatrogenic, and those not otherwise classified. Causes not otherwise classified can include conditions defined only by biochemical assays or those whose association with AUB is still poorly defined. Examples are isthmocele, arteriovenous malformations, and myometrial hypertrophy. Pregnancy is not considered in this system, but AUB is encountered in 15 to 20 percent of pregnancies (Everett, 1997; Weiss, 2004). Although frequently no reason is found in these cases, bleeding may reflect early abortion, ectopic pregnancy, cervical infection, gestational trophoblastic disease, cervical eversion, or polyp. Detailed discussions of bleeding associated with these are found in Chapters 6, 7, and 37.

DIAGNOSIS

History and Physical Examination

With AUB, the diagnostic goal is exclusion of pregnancy or cancer and identification of the underlying pathology to allow optimal treatment. During initial evaluation, a thorough patient history is collected. The menstrual history includes age at menarche, date of last menstrual period, birth control method, and the timing and amount of bleeding. A review of associated symptoms such as fever, fatigue, bulk symptoms, tissue passage, or pain can also direct evaluation. A family history inquires about members with AUB or other bleeding problems, and coagulopathy screening is described on page 193. Importantly, medications are reviewed, as abnormal bleeding can accompany the use of nonsteroidal antiinflammatory drugs (NSAIDs), anticoagulants, and agents with hyperprolactinemia as a potential side effect (Table 13-2, p. 285). Less robust evidence implicates herbal supplements that may affect coagulation, such as ginseng, garlic, ginkgo, dong quai, and St. John wort (Cordier, 2012).

Notably, most gynecologic disorders do not consistently display a specific bleeding pattern, and patients may complain of HMB or intermenstrual bleeding or both. Pain symptoms may be complex and include both cyclic and noncyclic patterns. Thus, the pattern for a particular woman may be of limited value in diagnosing the underlying cause of bleeding but can be used to assess improvement with treatment.

Of pain symptoms, dysmenorrhea often accompanies abnormal bleeding caused by structural abnormalities, infections, and pregnancy complications. This seems intuitive considering the role of prostaglandins in both HMB and dysmenorrhea. Painful intercourse and noncyclic pain are less frequent in women with AUB and usually suggest a structural or infectious source.

Gynecologic examination can also suggest an etiology. Moreover, it confirms the bleeding site as uterine, because vaginal, rectal, or urethral bleeding can present similarly. This is more difficult if there is no active bleeding, and urinalysis or stool guaiac evaluation can be helpful adjuncts.

In addition, blood tests, cervical cytology, sonography (with or without saline infusion), endometrial biopsy (EMB), and

hysteroscopy are used primarily. In many cases, not all of these tools are required and instead can be individually selected based on patient variables, suspected diagnosis, available resources, and provider training.

Laboratory Evaluation

β-Human Chorionic Gonadotropin and Hematologic Testing

Miscarriage, ectopic pregnancies, and gestational trophoblastic disease can present with AUB and may cause life-threatening hemorrhage. Pregnancy complications are quickly excluded with determination of urine or serum β-human chorionic gonadotropin (hCG) levels. This test is typically obtained on all reproductive-aged women with a uterus.

In women with AUB, a complete blood count (CBC) will identify anemia, the degree of blood loss, and platelet count extremes. With chronic loss, erythrocyte indices will reflect a microcytic, hypochromic anemia and show declines in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Moreover, in women with classic iron-deficiency anemia from chronic blood loss, an elevated platelet count can be seen. In those for whom the cause of anemia is unclear, those with profound anemia, or those who fail to improve with oral iron therapy, iron studies are often indicated. Specifically, iron-deficiency anemia produces low serum ferritin and low serum iron levels but an elevated total iron-binding capacity. Laboratory testing for disordered hemostasis is considered for those taking anticoagulant agents or in women and adolescents with HMB and no other obvious cause.

Cervicitis Evaluation

Cervicitis often causes intermenstrual or postcoital spotting. Accordingly, microscopic examination of a saline preparation of cervical secretions, or "wet prep," can be informative. With mucopurulent discharge, sheets of neutrophils (>30 per high-power field) and red blood cells are typical. With trichomoniasis, motile trichomonads are found. Cervicitis-related bleeding is frequently reproduced during sampling from an inflamed cervix with a friable epithelium.

The association between mucopurulent cervicitis and cervical infection with *Chlamydia trachomatis* and *Neisseria gonorrhoeae* is well established (Brunham, 1984). Thus, the Centers for Disease Control and Prevention (CDC) (2015) recommend testing for both when mucopurulent cervicitis is found (Chap. 3, p. 66). Moreover, even without frank discharge, these organisms can cause endometritis (Wiesenfeld, 2002). Thus, bleeding or spotting alone may merit screening for these two infections in at-risk populations (Table 1-1, p. 4). Last, herpes simplex virus (HSV) may manifest as diffuse erosive and hemorrhagic ectocervical lesions. In patients with such findings who lack a known HSV history, swab of the lesion for polymerase chain reaction (PCR) or serologic testing can be obtained.

Cervical Cytology or Biopsy

Both cervical and endometrial cancers can bleed, and evidence for these tumors may be detected during diagnostic Pap testing. The most frequent abnormal cytologic results involve squamous cell pathology and may reflect cervicitis, intraepithelial neoplasia, or cancer. Less commonly, atypical glandular or endometrial cells are found. Thus, depending on the cytologic results and patient age, colposcopy with ectocervical biopsy, endocervical curettage, and/or EMB may be indicated as discussed in Chapter 29 (p. 633). Moreover, at times, a visibly suspicious vaginal or cervical lesion may bleed and warrant direct biopsy with Tischler forceps.

Endometrial Biopsy

Indications. In many women, endometrial pathology underlies their AUB. These endometrial entities can be divided theoretically into focal lesions (leiomyoma, polyp) or more global conditions (hyperplasia, cancer, endometritis). This artificial division can aid diagnostic tool selection. Namely, some modalities have greater sensitivity for focal disease detection, whereas others are more sensitive for global pathology. That said, no tool, including transvaginal sonography, is recommended for routine endometrial cancer screening in asymptomatic low-risk women (Smith, 2018).

With endometrial cancer, AUB is noted in most affected women. The incidence and risk of this cancer rises with age, and most affected women are postmenopausal (Siegel, 2019). Thus, in postmenopausal women with AUB, the need to exclude cancer intensifies, and EMB is typically indicated. Of premenopausal women with endometrial neoplasia, most are obese or have chronic anovulation or both. Specifically, the American College of Obstetricians and Gynecologists (2016a) recommends endometrial assessment in any woman older than 45 years with AUB. Endometrial sampling is also reasonable in those younger than 45 with failed initial medical management, persistent AUB, or a history of unopposed estrogen exposure such as seen in obesity or polycystic ovarian syndrome (PCOS). Other risk factors include diabetes, tamoxifen use, and genetic predisposition to uterine cancer (American College of Obstetricians and Gynecologists, 2015). Genetic syndromes and their corresponding genes include hereditary non-polypoid cancer of the colon or Lynch syndrome (*MLH1*, *MSH2, MSH6, PMS2*); Peutz-Jeghers (*STK11*); Cowden (*PTEN*); Li-Fraumeni (*TP53*); and polymerase proofreading-associated polyposis (*POLD1*) (Ring, 2017).

Sampling Methods. With endometrial sampling, diagnostic accuracy correlates positively with the amount of endometrial tissue collected (Reijnen, 2017). Thus, a preferred screening tool collects as much tissue as possible for evaluation. Also, both focal and global lesions ideally would be identified. Last, patient comfort, cost, inability to enter the cavity, and rates of insufficient tissue are factored.

For years, dilation and curettage (D & C) has been used for endometrial sampling. It offers a high rate of access to the endometrial cavity, and in one study, the inability to biopsy was only 0.5 percent (Hefler, 2008). Its sensitivity for endometrial hyperplasia or cancer exceeds 90 percent (Sany, 2012; Yarandi, 2010). That said, blind sampling can be incomplete and can miss pathology (Stock, 1975). This is especially true for focal lesions (Bettocchi, 2001). D & C also has associated surgical risks, expense, postoperative pain, and need for operative anesthesia. For these reasons, other suitable in-office substitutes have been evaluated.

FIGURE 8-3 Endometrial sampling devices. **A.** Pipelle fluted tip. **B.** Novak curette tip. **C.** Kevorkian curette tip. **D.** Pipelle suction device.

Early office techniques used metal curettes, and Novak and Kevorkian curettes are examples (Fig. 8-3). Endometrial samples that are removed with these devices show significant positive correlation with histologic results obtained from hysterectomy specimens (Stovall, 1989). Thus, they are deemed adequate biopsy methods (Ferenczy, 1979). Disadvantages include patient discomfort and rare procedural complications such as uterine perforation and infection.

To minimize these, flexible plastic samplers have been evaluated for EMB. Advantageously, samples from these catheters have histologic findings for global pathology that are comparable with tissues obtained by D & C, hysterectomy, or stiff metal curette (Dijkhuizen, 2000; Stovall, 1991). Moreover, they afford greater patient comfort compared with D & C or in-office metal curettage. Of these disposable samplers, the Pipelle device is widely used (see Fig. 8-3).

Prior to performing EMB, pregnancy is excluded in women of reproductive age. With device insertion, patients frequently note cramping, which can be allayed by an oral preprocedural NSAID. For some, slow transcervical intrauterine instillation of 5 mL of 2-percent lidocaine solution using an 18-gauge angiocatheter can lower perceived pain scores (Dogan, 2004; Güler, 2010). Alternatively, 2-percent lidocaine gel can be applied, 1 mL at the tenaculum site and 2 mL into the endocervical canal (Karaca, 2016).

To begin, a speculum is placed, and the cervix is cleansed with an antibacterial solution, such as povidone-iodine solution. In many cases, a single-tooth tenaculum is needed to stabilize the cervix and permit passage of the Pipelle through the cervical os and into the endometrial cavity. When placing the tenaculum on the anterior cervical lip, closing the clamp slowly can decrease patient discomfort.

With sampling, the Pipelle is directed toward the fundus until resistance is met. Markings on the Pipelle allow measurement of uterine depth, and this value is recorded in the procedure note. The inner Pipelle stilette is then retracted to create suction within the cylinder. Several times, the Pipelle is withdrawn to the level of the internal cervical os and advanced back to the fundus. The device is gently turned during its advancement and retraction to allow thorough sampling of all endometrial surfaces. Once filled, the Pipelle is removed and its contents are emptied into a formalin-filled collection jar. The Pipelle tip should not be dipped into the formalin prior to reinsertion. Two to three insertions are performed to aid adequate sampling. Rarely, a vagal response can follow device insertion. In this instance, the procedure is terminated, and patient support is provided.

Despite its advantages, the Pipelle device does have limitations. First, a tissue sample may be *insufficient* or *scant* for histologic evaluation, and these are considered inadequate. In postmenopausal women, a significant percentage is subsequently found to have endometrial cancer or hyperplasia (Goebel, 2019; Kandil, 2014). For these inadequate samples in a postmenopausal patient with a low cancer risk, TVS is reasonable. A thin endometrial stripe typically reflects atrophy, and no further sampling is usually required if bleeding resolves. In these low-risk women, if a focal lesion is identified sonographically, hysteroscopy may be preferred. For an inadequate sample in those who carry a higher cancer risk and thus are better served by tissue biopsy, D & C offers higher rates of sufficient sampling (Arafah, 2014). Concurrent hysteroscopy during D & C can screen for focal lesions.

Premenopausal women with an inadequate sample are best served by D & C with hysteroscopy. Remember that patients in this group were initially sampled because of their inherent risks for endometrial cancer. That said, preoperative TVS can be added to help identify other possible AUB etiologies in this demographic.

A second limitation of Pipelle sampling is an inability to access the cavity. For example, cervical stenosis may obstruct sampling and techniques to overcome this are found in Chapter 41 (p. 903). A submucous leiomyoma near the isthmus is another frequent obstruction. Risks for stenosis include postmenopausal status, nulliparity, and prior cervical surgeries (Williams, 2008; Xie, 2018). With cervical stenosis, a second attempt following cervical ripening is common. A second failed EMB attempt or uterine myoma merits further investigation by D & C plus diagnostic hysteroscopy.

A third concern is the imperfect negative predictive value of Pipelle EMB. In one metaanalysis, the cancer-detection failure rate was 0.7 percent for all women biopsied (Clark, 2002a). Thus, a positive histologic result is accurate to diagnose cancer, but a negative result does not definitively exclude it. Therefore, if an EMB with normal tissue is obtained, but abnormal bleeding continues despite conservative treatment, or if the suspicion of endometrial cancer is high, then further sampling efforts are warranted.

Finally, endometrial sampling is associated with a greater percentage of false-negative results with focal pathology such as endometrial polyps (Demirkiran, 2012; Svirsky, 2008; Xie, 2018). Because of all these limitations with endometrial sampling, investigators have evaluated sonography, hysteroscopy, or both to replace or complement it.

In addition to the Pipelle device, the Tao Brush is another sampler. Once intracavitary, its long, bristled brush is rotated for sampling. Whereas the Pipelle obtains tissue for histologic examination, the Tao brush provides a specimen for cytologic evaluation. Although sensitivity values appear comparable to other techniques, this sampling method has not been widely adopted (Abdelazim, 2015; Del Priore, 2001).

Sonography

Transvaginal Sonography

Transvaginal sonography (TVS) is a widely available, cost-effective tool that is commonly used to evaluate AUB. TVS can be an adjunct to both EMB and hysteroscopy when evaluating the endometrium. However, because of greater patient comfort and improvements in imaging resolution, TVS is also frequently used as a primary diagnostic modality. Another advantage of TVS is its ability to assess the myometrium, uterine surfaces, and adnexa. As such, it offers anatomic information not afforded by hysteroscopy or EMB. Namely, pathology such as leiomyomas, adenomyosis, or estrogen-producing stromal ovarian tumors can be identified.

For *endometrial lesions*, TVS is most helpful and sensitive to define endometrial thickness. Imaged in a sagittal view, this thickness represents the opposed endometrial surfaces and appears as a hyperechoic endometrial stripe down the center of the uterine body (Fig. 8-4 and Fig. 2-16, p. 38). Intracavity fluid, if present, is not included in the calculation. Instead, the endometrial thickness on each side of the fluid is measured and then summed. Factors that can limit visualization and accuracy of endometrial measurement include patient obesity and other uterine pathology such as myomas and adenomyosis. In both premenopausal and postmenopausal women, a thick endometrium may reflect global pathology, or it may signal a focal lesion. However, the sensitivity of TVS to differentiate the two is poor. In such cases, saline-infusion sonography (SIS) or hysteroscopy, which are more effective for identifying focal lesions, can be informative.

In *postmenopausal women with AUB*, endometrial thickness has been correlated with endometrial cancer risk. Thickness measurements of 3.4 ± 1.2 mm typically reflect an atrophic endometrium, whereas much greater thicknesses correlate with endometrial hyperplasia, intraepithelial neoplasia, and endometrial cancer (Granberg, 1991). For endometrial cancer, negative predictive values >99 percent have been reported using a measurement ≤4 mm (Karlsson, 1995; Tsuda, 1997). This threshold does not appear to be affected by hormone replacement therapy (HRT) use (Smith-Bindman, 1998). In those using cyclic HRT, TVS is best performed 4 or 5 days following cycle bleeding cessation (Goldstein, 2001). For postmenopausal women with AUB, an endometrial thickness >4 mm typically requires additional evaluation with SIS, hysteroscopy, or EMB.

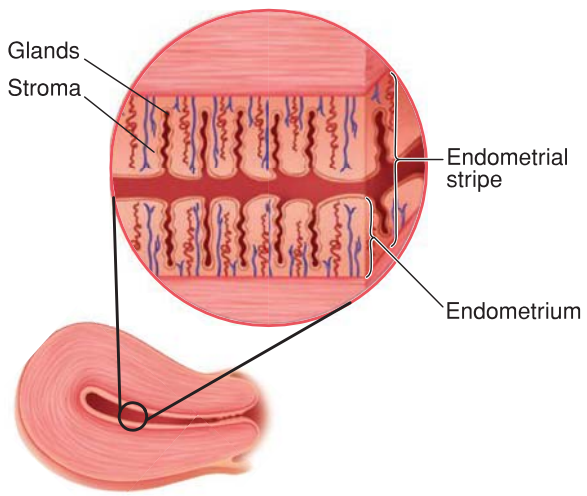

FIGURE 8-4 The sonographic endometrial stripe in a sagittal plane represents the thickness created by the apposed anterior and posterior endometrium. In premenopausal women, stripe thickness will vary during the menstrual cycle as the endometrium gradually thickens and then is sloughed.

Although these criteria can safely reduce EMB rates for many patients, others consider false-negative rates too high with this strategy. In one retrospective cohort of 4000 postmenopausal women with bleeding, the sensitivity to diagnose endometrial cancer was 97 percent for a thickness ≤3 mm but 94 percent for a threshold of ≤4 mm (Wong, 2016). This was similar to a metaanalysis by Timmermans and associates (2010). In addition, in diabetic or obese women, the 4-mm guideline may be less predictive (van Doorn, 2004). Because of these concerns, some advocate hysteroscopy with direct biopsy or endometrial sampling to evaluate all postmenopausal bleeding (Litta, 2005; Tabor, 2002).

For low-cancer-risk postmenopausal women *without bleeding*, the risk of cancer or hyperplasia is low. This includes those found to have an endometrial thickness above accepted thresholds (Fleischer, 2001; Jokubkiene, 2016). The American College of Obstetricians and Gynecologists (2018c) notes that an endometrial thickness >4 mm in this population need not routinely prompt evaluation. Instead, further testing is directed by coexistent patient risks. According to the decision analysis by Smith-Bindman and colleagues (2004), however, endometrial sampling is suitable for a threshold thickness value >11 mm in asymptomatic postmenopausal women. Focal lesions are common in this subgroup and can contribute to the endometrial thickness measurement. Thus, SIS or hysteroscopy may be favored if additional evaluation is indicated (Schmidt, 2009; Wong, 2016).

For *premenopausal women with AUB*, researchers have also attempted to create endometrial thickness guidelines. Merz and colleagues (1996) found that the normal endometrial thickness in premenopausal women did not exceed 4 mm on day 4 of the menstrual cycle, nor did it measure more than 8 mm by day 8. However, endometrial thicknesses can vary considerably among premenopausal women, and evidence-based abnormal thresholds that have been proposed range from ≥4 mm to >16 mm (Breitkopf, 2004; Goldstein, 1997; Shi, 2008). Thus, a consensus for endometrial thickness guidelines has not been established for this group.

In addition to thickness, other sonographic qualities of the endometrium are also considered when evaluating AUB. Standardization of terms and definitions for these have been proposed but have not been robustly validated (Leone, 2010; Sladkevicius, 2018). Of findings, punctate cystic areas within the endometrium may indicate a polyp. Hypoechoic masses that distort the endometrium and originate from the inner layer of myometrium most likely are submucous leiomyomas. In postmenopausal women, endometrial cavity fluid is common and typically benign (Bar-Hava, 1998; Vuento, 1996). No sonographic findings are specific to endometrial cancer, but some findings have been linked with greater frequency (Fig. 33-3, p. 702). For example, intermingled hypo- and hyperechoic areas within the endometrium and an irregular endometrial-myometrial junction may indicate malignancy. Thus, with these

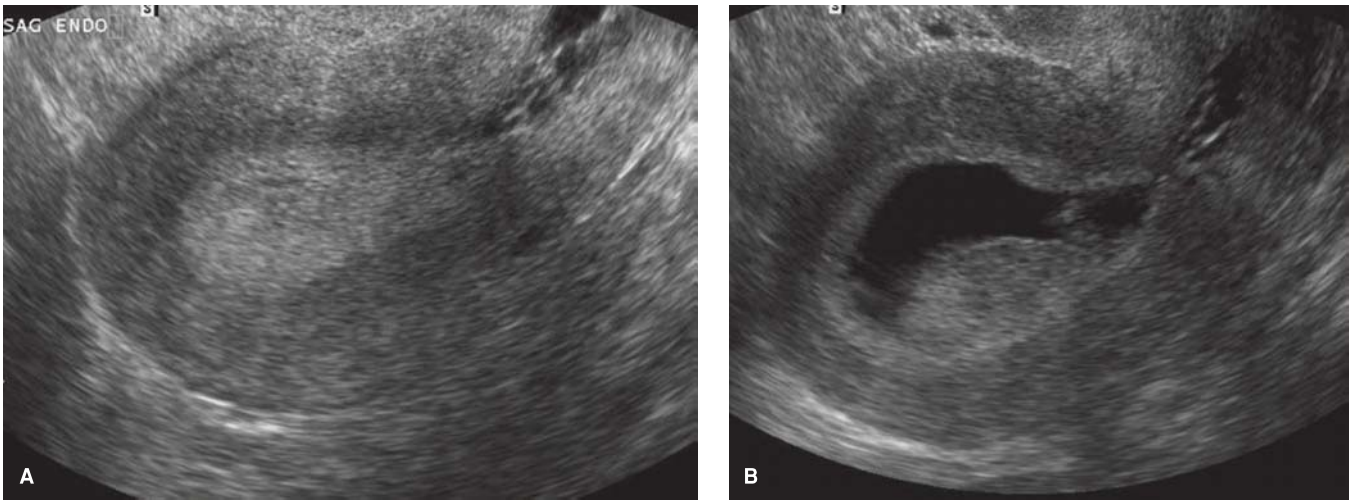

FIGURE 8-5 Transvaginal sonography of the uterus in the sagittal plane. **A.** The endometrium is thickened in this postmenopausal patient. **B.** Saline-infusion sonography reveals a posterior endometrial mass and further delineates its size and qualities. (Reproduced with permission from Dr. Elysia Moschos.)

findings, even with a normal endometrial thickness in postmenopausal patients, EMB or hysteroscopy with biopsy is considered to exclude malignancy (Sheikh, 2000).

Saline-Infusion Sonography

Also known as *sonohysterography* or *hysterosonography*, saline-infusion sonography (SIS) usually provides a detailed evaluation of the endometrial cavity (Chap. 2, p. 32). By distending the cavity with fluid, SIS allows identification of common endometrial masses associated with AUB. These lesions include endometrial polyps, submucous leiomyomas, and intracavitary blood clots, which all frequently create only a nondescript distortion or endometrial thickening when imaged with TVS (Fig. 8-5). Because SIS also images the myometrium, this modality can help differentiate lesions as being endometrial, submucous, or intramural.

To detect uterine cavitary focal lesions, SIS is often compared against hysteroscopy and provides similar diagnostic accuracy (Maheux-Lacroix, 2016; Seshadri, 2015). Importantly, neither can reliably discriminate between benign and malignant. Thus, because of the malignant potential of many focal lesions, biopsy or excision of most structural lesions, when identified, is recommended for those with risk factors. For this, operative hysteroscopy is typically used.

Although accurate for identifying focal lesions, SIS may not add to the value of TVS for evaluation of global lesions such as hyperplasia and cancer. Thus, in women with AUB for whom the exclusion of cancer is more relevant, SIS alone as an initial diagnostic tool may not have advantages over TVS.

SIS has other limitations. Contraindications include pregnancy, active pelvic infection, or stenosis (Chap. 2, p. 31). Additionally, SIS is cycle dependent and best performed in the proliferative phase of the menstrual cycle (American College of Obstetricians and Gynecologists, 2016b). By performing SIS prior to ovulation, interruption of an early pregnancy is avoided. Additionally, timing in the proliferative phase can minimize false-negative and false-positive results. Namely, a thick secretory endometrium may conceal or be mistaken for focal lesions such as small polyps or focal hyperplasia. In addition, SIS usually has more patient discomfort than TVS, and approximately 5 percent of examinations cannot be completed because of cervical stenosis or patient discomfort. As expected, stenosis is more prevalent in postmenopausal women, and the incompletion rate mirrors that of diagnostic hysteroscopy.

Other Sonographic Techniques

In selected instances, other imaging modalities can provide information beyond that obtained from TVS and SIS, and these are described in Chapter 2. Doppler technology can be applied to ultrasound to assess vascularity. For example, a feeding vessel supplying a focal endometrial mass supports the diagnosis of endometrial polyp. Similarly, 3-dimensional (3-D) sonography and 3-D SIS are most helpful to clarify focal endometrial lesions (Benacerraf, 2008; Makris, 2007). However, even with enhanced sonographic visualization, 3-D SIS does not appear superior to two-dimensional SIS for this indication (Nieuwenhuis, 2017). With power Doppler, findings of multiple irregularly branching vessels can suggest malignancy (Dueholm, 2014). 3-D power Doppler has been employed to differentiate malignant and benign endometrium, but its value is still undefined (Dueholm, 2015; Opolskiene, 2010). Last, although preferred to computed tomography (CT), magnetic resonance (MR) imaging is rarely needed for AUB evaluation. However, MR imaging can display the endometrium in cases in which sonographic views are obstructed and in which SIS or hysteroscopy is not possible (Bennett, 2011).

Hysteroscopy

With this procedure, a small-diameter endoscope is inserted into the endometrial cavity as explained in Chapter 41 (p. 899). The uterine cavity is then distended with saline or another medium for visualization. In addition, targeted hysteroscopic biopsy permits a histologic diagnosis of any abnormal areas (Ceci, 2002; Tinelli, 2008). Another main use of hysteroscopy is detection of focal intracavitary lesions, such as leiomyomas and polyps, which might be missed by EMB or TVS (Maheux-Lacroix,

2016; Tahir, 1999). When identified during hysteroscopy, these lesions can be simultaneously removed in the same session.

Because of these advantages, some advocate hysteroscopy as the primary tool for AUB diagnosis. However, the invasiveness and cost of hysteroscopy are balanced against improved diagnostic efficiency. Moreover, although accurate for identifying endometrial cancer, hysteroscopy is less accurate for endometrial hyperplasia or intraepithelial neoplasia (Gkrozou, 2015; Lasmar, 2006). Accordingly, some recommend EMB or endometrial curettage in conjunction with hysteroscopy (Ben-Yehuda, 1998; Clark, 2002b).

Hysteroscopy has other limitations. Cervical stenosis will sometimes block successful introduction of the endoscope. Alternatively, overdilation of the cervix may result in excessive backflow of the distention media and prohibit adequate distention of the cavity for viewing. Additionally, heavy bleeding may obscure and hinder an adequate examination. Hysteroscopy is also more expensive and technically challenging compared with TVS or SIS. Costs can be lowered if performed in the office rather than in an operative suite. However, patient discomfort may limit complete examination during some office procedures. Procedural pain may be diminished with use of a smaller diameter or flexible hysteroscope (Cicinelli, 2003; Paulo, 2015).

Another concern with hysteroscopy is the potential to seed the peritoneal cavity with malignant cells via retrograde flow of distention media through the fallopian tubes (Bradley, 2004; Zerbe, 2000). However, despite this, overall patient prognosis does not appear to be worsened in such cases (Chang, 2011; Soucie, 2012). The American College of Obstetricians and Gynecologists (2018a) considers hysteroscopy acceptable for AUB evaluation in those without advanced-stage uterine or advanced-stage cervical cancer.

Summary of Diagnostic Procedures

No one clear sequence of EMB, TVS, SIS, and hysteroscopy is superior during AUB evaluation. That said, TVS for several reasons is a logical first step. It is well tolerated, cost-effective, and requires relatively minimal technical skill (Figs. 8-6 and 8-7). In addition, it can reliably determine endometrial stripe thickness and whether a lesion is myometrial or endometrial. Once potential anatomic lesions have been identified, subsequent evaluation requires individualization. If endometrial hyperplasia or cancer is suspected, EMB offers advantages. Alternatively, possible focal lesions may be best investigated with hysteroscopy or SIS. Ultimately, the diagnostic goal is to identify and treat pathology and exclude endometrial neoplasia. Thus, test selection is guided by its accuracy in characterizing the most likely anatomic lesions, which are described in subsequent sections.

ENDOMETRIAL ABNORMALITIES

Hyperplasia and Intraepithelial Neoplasia

Several endometrial conditions linked with a relative estrogen excess can cause AUB. Estrogen promotes endometrial proliferation and growth, whereas progesterone limits this growth. With unbalanced estrogen stimulation, endometrial proliferation continues unchecked, leading to a spectrum of architectural and cytologic changes. These global conditions include disordered proliferative endometrium (DPE), endometrial hyperplasia without atypia, endometrial intraepithelial neoplasia (EIN), and endometrial cancer.

Remember that normal proliferative-phase endometrium contains regularly spaced glands that lie within stroma at a glands-to-stroma ratio of 1:1 (Fig. 33-1, p. 701). With DPE, the proliferative endometrium maintains this normal ratio overall but shows focal and mild gland dilation and crowding.

In contrast, *hyperplasia without atypia* shows more widespread gland crowding. Gland cytology is normal, and only occasional mitotic figures are seen. Hyperplasia without atypia is the term now recognized by the World Health Organization (WHO) and encompasses the former terms *simple hyperplasia without atypia* and *complex hyperplasia without atypia* (Zaino, 2014). Hyperplasia without atypia will typically regress after the unopposed estrogen environment is corrected. That said, 1 to 3 percent of untreated cases may progress to endometrioid adenocarcinoma.

EIN reflects a transition to a true premalignant lesion. It displays both gland crowding and abnormal gland nuclei. EIN comprises the former *simple hyperplasia with atypia* and *complex hyperplasia with atypia* (American College of Obstetricians and Gynecologists, 2017a). EIN significantly raises the risk of developing endometrial cancer, and its treatment is discussed in Chapter 33 (p. 703).

DPE and hyperplasia without atypia are best treated with progesterone. Common forms include oral medroxyprogesterone acetate (MPA), 10 to 20 mg daily; intramuscular DMPA, 150 mg every 3 months; or the levonorgestrel-releasing intrauterine system (LNG-IUS). Megestrol acetate, 40 to 200 mg orally daily, is also effective but used less frequently and mainly in those with EIN (Trimble, 2012). Consensus is lacking on optimal treatment length and route. That said, one randomized study showed the LNG-IUS or a continuous daily oral 10-mg dose of MPA was more effective in reestablishing a normal endometrium than was cyclic oral MPA (Ørbo, 2014).

To document resolution of hyperplasia without atypia, rebiopsy is recommended following progestin treatment and a subsequent withdrawal bleeding. However, consensus as to rebiopsy timing is lacking, and retesting after 3 to 6 months of treatment is used at our institution. Once normal endometrium is reestablished, no additional sampling is required unless new bleeding develops. Importantly, unless the underlying cause of unopposed estrogen is corrected, long-term progestin therapy is considered. Relapse rates following progestin discontinuation are high (Ørbo, 2016).

Metaplasia

Tissues derived from the müllerian ducts have remarkable capacity to undergo transformation into various epithelial types. This transformation is termed *metaplasia.* Endometrial metaplasia involving architecturally normal, or simple, glands usually reflects a benign reactive or hormonally driven process within the endometrium. However, endometrial metaplasia can also arise in association with EIN and endometrial adenocarcinoma (Carlson, 2008; Nicolae, 2011). Thus, if metaplastic change is associated with architectural abnormalities diagnostic of, or suspicious for, EIN or endometrial adenocarcinoma, further endometrial evaluation is warranted.

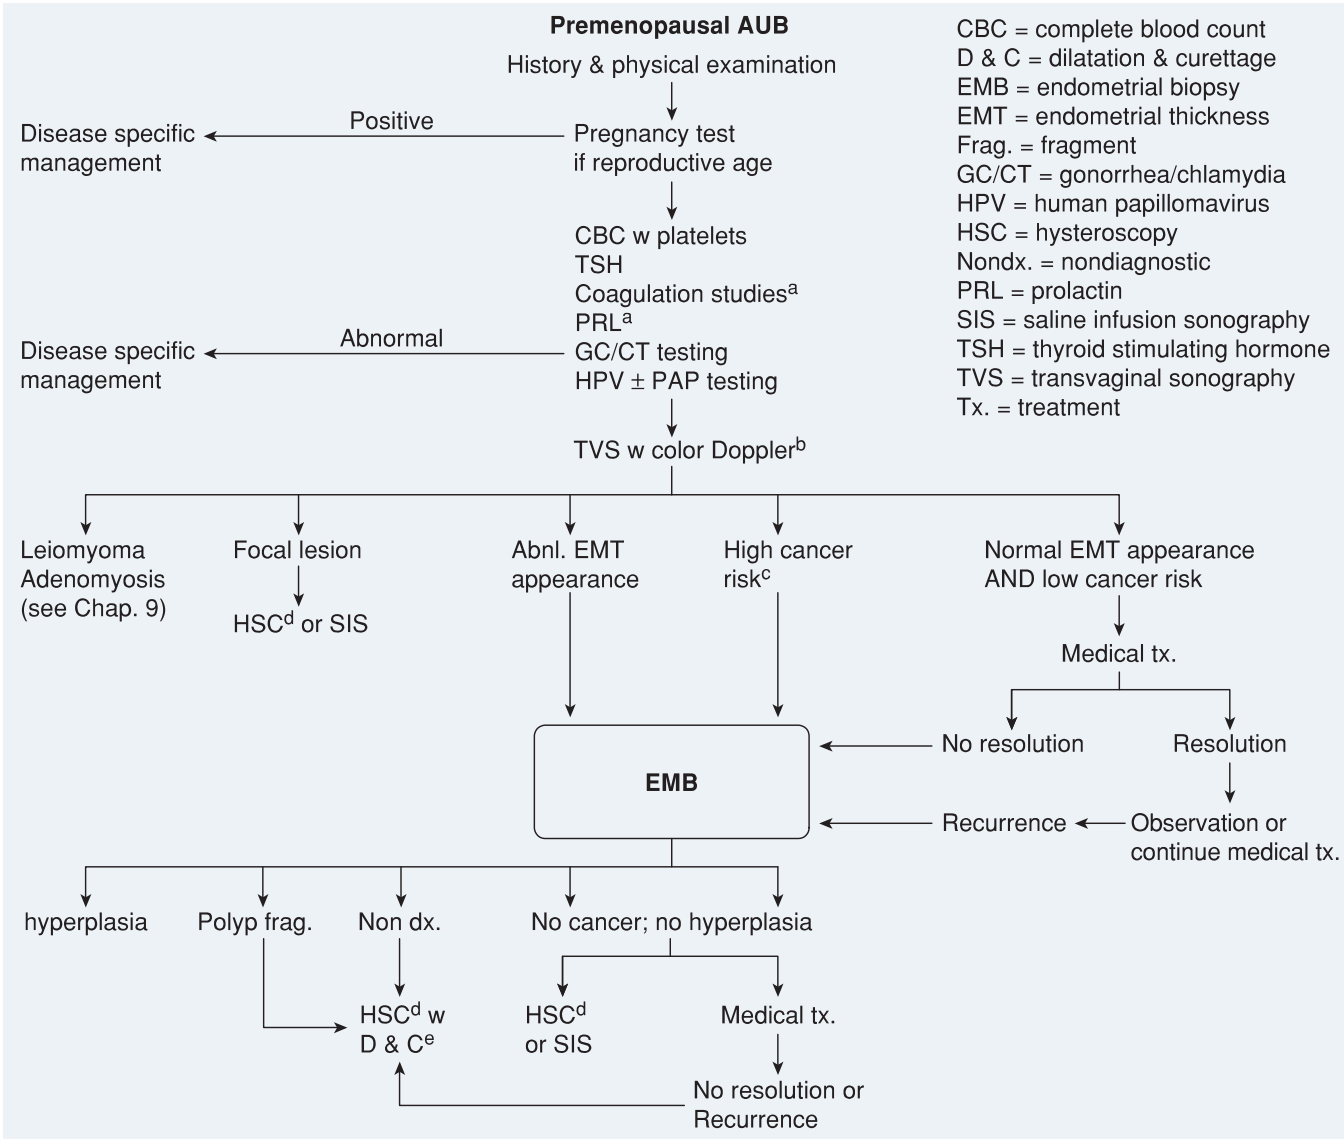

FIGURE 8-6 Diagnostic algorithm to identify endometrial pathology in premenopausal patients with abnormal uterine bleeding.

[b]When indicated, EMB as a primary step is suitable in settings without readily available TVS.
[c]Patients with chronic anovulation, obesity, ≥45 years of age, PCOS, tamoxifen use, diabetes, nulliparity, late menopause, unopposed estrogen use, and predisposing genetic syndromes.
[d]Other endoscopic devices to visualize the endometrial cavity are suitable.
[e]Depending on clinical setting, direct hysteroscopic sampling may suitably replace D & C.

Endometrial reactive changes comprise a heterogeneous group of endometrial morphology that can be associated with hormonal imbalance or recent inciting events such as infection, stromal breakdown, pregnancy, or instrumentation (Quick, 2018). Reactive changes are uncommonly linked to malignancy unless architectural abnormalities characterizing EIN or endometrial adenocarcinoma are also present (Nicolae, 2011).

Endometritis

In addition to cervicitis (p. 183), chronic endometritis has been linked to AUB in some but not all studies (Greenwood, 1981; Pitsos, 2009). Underlying infection is often implicated, and agents of bacterial vaginosis, *Mycoplasma* species (spp.), *Streptococcus* spp., certain coliforms, *N gonorrhoeae*, and *C trachomatis* have each been identified (Cicinelli, 2008; Wiesenfeld, 2002). Thus, gonorrhea and chlamydial infection screening is reasonable in many sexually active patients with AUB, and positive results prompt treatment per CDC guidelines (2015) (Tables 3-9 and 3-11, p. 70). In other cases, chronic endometritis is linked to a structural cause such as endometrial polyp, intrauterine device (IUD), or submucous leiomyoma. It may also follow abortion or pregnancy.

Chronic endometritis is traditionally diagnosed histologically by plasma cell infiltration. In women undergoing diagnostic hysteroscopy, endometrial hyperemia, edema, and "micropolyps" measuring <1 mm can also suggest the diagnosis (Cicinelli, 2005).

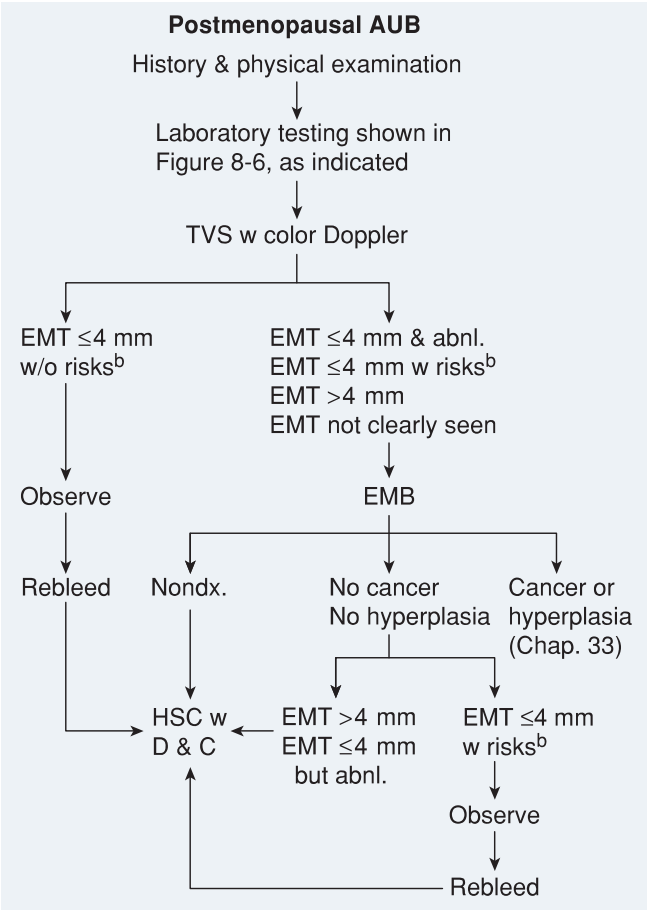

FIGURE 8-7 Diagnostic algorithm to identify endometrial pathology in postmenopausal patients with abnormal uterine bleeding.
[a]Study obtained as indicated by patient history.
[b]Chronic anovulation, obesity, ≥45 years of age, polycystic ovarian syndrome, tamoxifen use, diabetes, nulliparity, late menopause, unopposed estrogen use, and predisposing genetic syndromes.

Because infection may or may not underlie all cases of chronic endometritis, the decision to prescribe antibiotics can be challenging. And, few studies have evaluated the efficacy of antibiotics to resolve bleeding symptoms. At our institution, patients with documented histologic findings of endometritis are typically given a course of doxycycline, 100 mg orally twice daily for 10 days.

STRUCTURAL ABNORMALITIES

Uterine Enlargement

Structural abnormalities are frequent causes of AUB, and leiomyomas are by far the most common. Myomas, adenomyosis, and isthmoceles are presented in Chapter 9. Uterine and cervical neoplasms are discussed in Chapters 30, 33, and 34. As described in Chapter 19, partially obstructive congenital reproductive tract anomalies may at times cause chronic intermenstrual bleeding superimposed on normal menstrual cycling. Endometrial and endocervical structural abnormalities such as polyps and arteriovenous malformations are described here.

Endometrial Polyp

These soft, fleshy intrauterine growths are composed of endometrial glands, fibrous stroma, and surface epithelium. Intact polyps may be single or multiple, measure from a few millimeters to several centimeters, and be sessile or pedunculated (Fig. 8-8). Estrogen and progesterone are implicated in their growth, as higher receptor levels are noted within polyps compared with adjacent normal endometrium (Peres, 2018).

Polyps are common, and their prevalence in the general population approximates 9 percent (Dreisler, 2009a). In those with AUB, rates range from 10 to 30 percent (Bakour, 2000; Goldstein, 1997). Risk factors for developing endometrial polyps include increasing age, obesity, and tamoxifen use (Reslova, 1999). Although some studies suggest an association between HRT and polyp formation, others do not (Bakour, 2002; Dreisler, 2009a; Maia, 2004; Oguz, 2005). However, use of oral contraceptive pills appears to be protective (Dreisler, 2009b). For women taking tamoxifen, the LNG-IUS lowers endometrial polyp and endometrial hyperplasia rates. With LNG-IUS use, breast cancer recurrence rates are not higher in the short term, however long-term data are lacking regarding recurrence (Dominick, 2015).

Women with endometrial polyps may have no complaints, and polyps are identified during imaging for other indications (Goldstein, 2002). When symptomatic, polyps are frequently associated with HMB, prolonged bleeding, or intermenstrual bleeding. Infertility has also been linked indirectly with endometrial polyps. For example, small studies have shown higher pregnancy rates and fewer early pregnancy losses in infertile

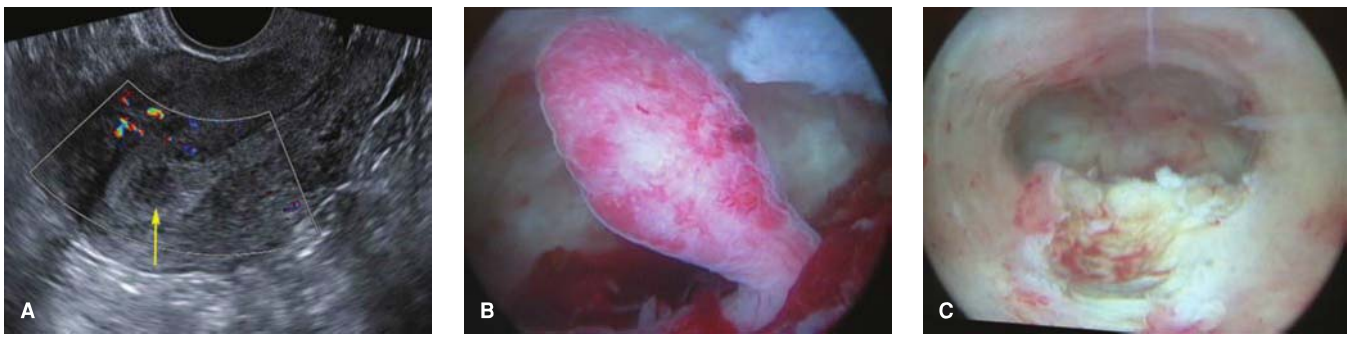

FIGURE 8-8 Endometrial polyp. **A.** Sagittal image of a uterus using transvaginal sonography with color Doppler. The yellow arrow points to the polyp, which is hypoechoic compared with the surrounding endometrium. **B.** Hysteroscopic image of same polyp. **C.** Endometrial cavity following polyp resection. women following hysteroscopic polyp excision (Pérez-Medina, 2005; Preutthipan, 2005; Stamatellos, 2008).

The main diagnostic tools include TVS with applied color Doppler, SIS, and hysteroscopy. In premenopausal women, TVS is best performed prior to day 10 of the cycle to lower the risk of false-positive findings from a normally thick secretory endometrium. With TVS, an endometrial polyp may appear as a nonspecific endometrial thickening or as a rounded hyperechoic mass within the cavity. Sonolucent cystic spaces corresponding to dilated endometrial glands are seen within some polyps. Importantly, polyps may appear similar to intracavitary myomas. To help differentiate the two, TVS can be augmented with color or power Doppler. Endometrial polyps typically have only one arterial feeding vessel, whereas submucous leiomyomas generally received blood flow from several vessels arising from the inner myometrium (Fig. 8-9) (Cil, 2010; Fleischer, 2003).

SIS and hysteroscopy are both accurate in identifying endometrial polyps (Bittencourt, 2017; Soares, 2000). With SIS, polyps appear as echogenic, smooth, intracavitary masses with either broad bases or thin stalks (see Fig. 8-5B). With hysteroscopy, nearly all cases are identified with the added ability to remove the polyp concurrently.

The Pap test is an ineffective tool to identify polyps. However, 5 percent of postmenopausal women with benign endometrial cells detected on Pap testing are found to have endometrial polyps (Karim, 2002). Moreover, in postmenopausal women with atypical glandular cells of undetermined significance (AGUS), endometrial polyps were the most frequent underlying pathology found (Obenson, 2000).

EMB or D & C may also identify polyps. However, as previously discussed, blind sampling may completely miss or incompletely sample focal lesions.

Management of endometrial polyps is directed by symptoms and malignancy risk. Most polyps are benign, and premalignant or malignant transformation develops in only approximately 5 percent (Baiocchi, 2009; Ricciardi, 2014). The most consistent risks for transformation are postmenopausal status, age older than 60, and abnormal bleeding. Some supporting data suggest that larger polyp size (>1.5 cm), tamoxifen use, diabetes, and obesity also confer a higher risk (Ferrazzi, 2009; Sasaki, 2018). Thus, operative hysteroscopic polypectomy may be most effective for symptomatic women or those with risk factors for malignant transformation. Procedural steps are described in Chapter 44 (p. 1056). During polypectomy, targeted sampling of the remaining endometrium is considered in those with endometrial cancer risk factors or with risks for malignant transformation within the polyp (Rahimi, 2009). Endometrial sampling during all polypectomy procedures also is reasonable, as previously undiagnosed endometrial cancer was found in 0.5 percent of more than 6000 women younger than 45 undergoing endometrial polypectomy (Yuk, 2018). Following polypectomy, subsequent polyp recurrence rates vary widely and can reach 45 percent (Gu, 2018; Yang, 2015).

Findings within a polyp are treated similarly to results found in nonpolypoid endometrium. For example, with polyps containing atypical hyperplasia, comorbid atypical hyperplasia or cancer in the remaining endometrium is found in one half to two thirds of hysterectomy specimens (Mittal, 2008; Naaman, 2015).

For asymptomatic women with small polyps and no malignant transformation risk factors, management can be more conservative (American Association of Gynecologic Laparoscopists, 2012). Some advocate removal of all endometrial polyps because premalignant and malignant transformation has been identified in even asymptomatic premenopausal women (Golan, 2010). However, the transformation risk in these patients with lesions measuring <15 mm is low (Ben-Arie, 2004). In addition, many polyps ≤10 mm will spontaneously resolve or slough (DeWaay, 2002; Wong, 2017). If conservative observation is elected, the optimum surveillance regimen for these women remains undefined.

Endocervical Polyp

These lesions represent overgrowths of benign endocervical stroma covered by mucinous columnar epithelium. They typically appear as single, red, smooth, elongated masses extending from the endocervical canal (Fig. 8-10). Polyps vary in size and

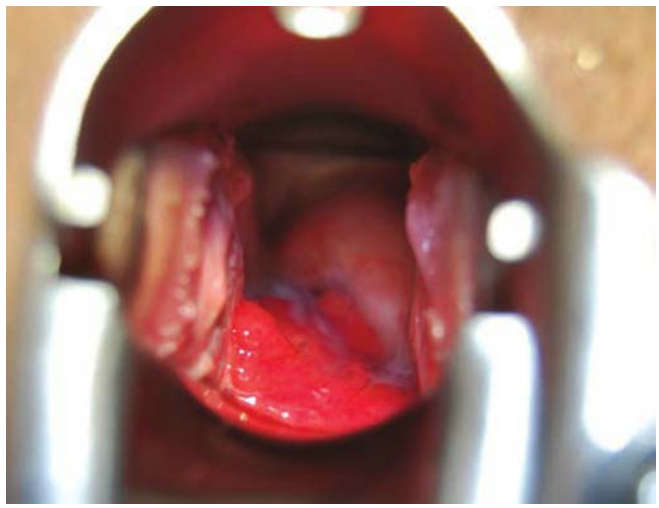

FIGURE 8-10 This endocervical polyp has a typical color and texture but is longer than most of these polyps.

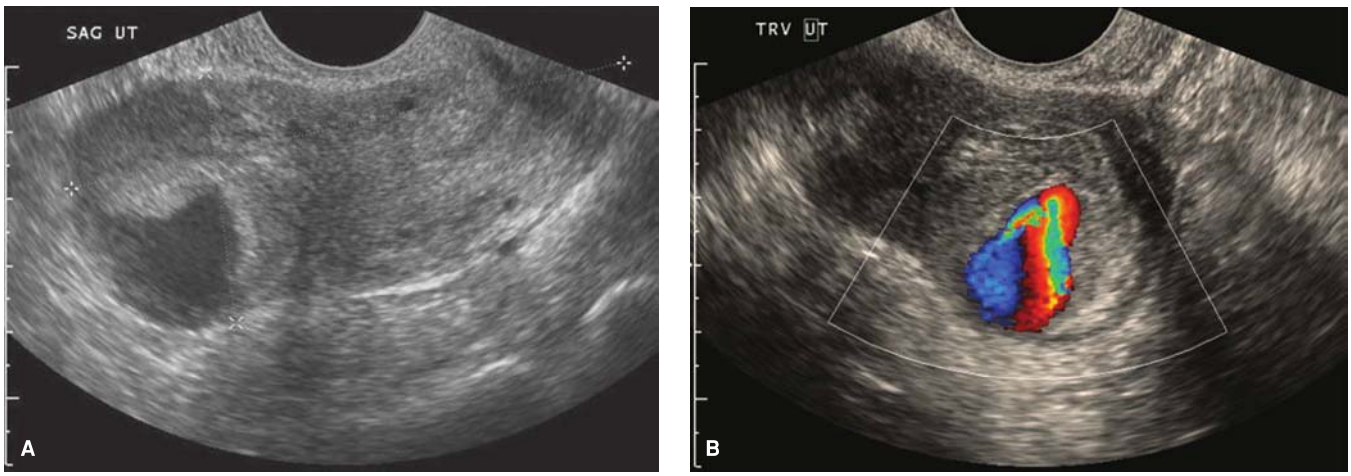

FIGURE 8-11 Transvaginal sonography of an arteriovenous malformation (AVM). **A.** Sagittal image of the uterus (*calipers*) with an irregular-shape anechoic space within the posterior fundal myometrium. **B.** Color Doppler evaluation of this area in the transverse plane demonstrates the classic mosaic color pattern of an AVM. (Reproduced with permission from Dr. Elysia Moschos.)

range from several millimeters to 2 or 3 cm. These common growths are found more frequently in multiparas and rarely in prepubertal females. Endocervical polyps are usually asymptomatic, but they can cause intermenstrual or postcoital bleeding or symptomatic vaginal discharge. Many endocervical polyps are identified by visual inspection during pelvic examination. In other instances, AGUS Pap smear findings may prompt investigation and lead to identification of endocervical polyps higher in the endocervical canal (Burja, 1999).

Endocervical polyps are typically benign, and premalignant or malignant transformation develops in less than 1 percent (Chin, 2008; Schnatz, 2009). However, cervical cancer can present as polypoid masses and can mimic these benign lesions. Others in the differential diagnosis include condyloma acuminata, leiomyoma, decidua, granulation tissue, or fibroadenoma. Most recommend removal and histologic evaluation of all polypoid lesions. However, studies have stratified affected patients by symptoms and cytology and found no preinvasive disease or cancer in endocervical polyps of asymptomatic women with normal cervical cytology (Long, 2013; MacKenzie, 2009).

For removal, if the stalk is slender, endocervical polyps are grasped by ring forceps. The polyp is twisted repeatedly about the base of its stalk. With repeated twisting, feeding vessels are strangulated, and its base will narrow and avulse. Monsel paste (ferric subsulfate) can be applied with direct pressure as needed to the resulting stalk stub to complete hemostasis. A thick pedicle may warrant surgical ligation and excision if heavier bleeding is anticipated. Patients are counseled that endocervical polyp recurrence rates range from 6 to 15 percent (Berzolla, 2007; Younis, 2010).

Arteriovenous Malformation

These rare structures contain a mixture of arterial, venous, and small capillary-like channels with fistulous connections. Uterine arteriovenous malformations (AVMs) may be congenital or acquired, and vessel sizes can vary considerably. Acquired AVMs are usually large vessels that develop after myometrial or intracavitary uterine surgery. Concurrent cervical or endometrial cancer, gestational trophoblastic disease, or IUD use are other associations (Ghosh, 1986). Uterine AVMs more frequently involve the corpus, but they may also be found in the cervix (Lowenstein, 2004). Affected patients often note HMB and perhaps intermenstrual bleeding that is unprovoked or that is triggered by a spontaneous miscarriage, curettage, or other intracavitary uterine surgery. Symptoms can appear slowly or suddenly with life-threatening hemorrhage (Timmerman, 2003).

In some cases, AVMs are first visualized with TVS because of its ready availability and widespread use. Sonographic characteristics are nonspecific and may include anechoic tubular structures within the myometrium (Fig. 8-11). Color Doppler or power Doppler ultrasound may provide a more specific image with bright, large-caliber vessels and multidirectional flow (Tullius, 2015). Angiography aids confirmation and can be used concurrently to perform vessel embolization (Cura, 2009). CT scanning with contrast, MR imaging, SIS, and hysteroscopy have also been used to image these.

AVMs are effectively treated by hysterectomy. Arterial embolization is another potential option (Barral, 2017). In one systematic review, the success rate with embolization was a 91 percent. A second embolization was required in some cases (Yoon, 2016).

EXTERNAL SOURCES

Intrauterine Device

The copper-containing IUD (ParaGard) alone can cause HMB or intermenstrual bleeding, but concurrent pregnancy, infection, or malpositioned device is first sought. Their management is discussed in Chapter 5 (p. 114). Once these are excluded, other AUB sources are investigated. With TVS, endometrial stripe evaluation may be limited by IUD shadowing. If needed, EMB with small catheters can be performed without device removal (Dean, 2018).

HMB attributed solely to a copper IUD can be treated or prevented with an empiric trial of NSAIDs taken during menses (Grimes, 2006). Intermenstrual bleeding, however, is typically not improved with these agents (Godfrey, 2013). For HMB treatment or prevention, limited evidence also supports tranexamic acid (Alanwar, 2018; Ylikorkala, 1983).

With the LNG-IUS, unscheduled spotting or light bleeding is expected during the first several months and decreases with continued use (Curtis, 2016b). Over time, the endometrium atrophies and leads to progestin-induced amenorrhea (McGavigan, 2003). However, if needed, treatment options mirror those for the copper IUD.

Hormonal Therapy

Other hormonal birth control methods typically lighten menstrual flow. However, breakthrough bleeding can be a common cause of early discontinuation.

With combination oral contraceptive (COCs), intermenstrual bleeding typically occurs early during use, and reassurance alone is suitable. Also, a medication inventory can identify new medications that might lower COC efficacy to incite such bleeding (Table 5-8, p. 124). If persistent, intermenstrual bleeding can typically be corrected by changing to a formulation with a higher estrogen dose (Table 5-6, p. 121).

In contrast, users of progestin-only contraceptive methods can experience breakthrough bleeding throughout the duration of use. Although this often improves with time, chronic breakthrough bleeding with these methods can be lessened by an estrogen supplement such as an oral daily 2-mg estradiol dose or 1.25-mg conjugated equine estrogen dose for 1 to 2 weeks. Alternatively, a COC can be added for 1 to 3 cycles (Zigler, 2017).

With *hormone replacement therapy*, irregular spotting or bleeding is also a well-known early side effect. With continuous therapy, lower initial doses may cause less estrogen stimulation of the endometrium and thus result in less bleeding (Archer, 2011). Importantly, compared with women on HRT who have attained amenorrhea, intrauterine pathology is four times more frequent in patients with continued abnormal bleeding past the first 6 months of HRT use and in those who have abnormal bleeding after achieving initial amenorrhea (Leung, 2003). Thus, further evaluation of AUB in these postmenopausal women should be considered.

Of the *selective estrogen-receptor modulators (SERMs)*, raloxifene, ospemifene, and bazedoxifene can each result in postmenopausal bleeding. However, this is much less frequent than with HRT (Christodoulakos, 2006; Kagan, 2018; Simon, 2013). These agents are discussed in Chapter 22.

Another SERM, tamoxifen, is used as an adjunct for treatment of estrogen-receptor-positive breast cancer. Although it diminishes estrogen action in breast tissue, tamoxifen stimulates endometrial proliferation. This SERM has been linked to hyperplasia, polyps, and adenocarcinoma of the endometrium and to uterine sarcomas (Cohen, 2004). Thus, in women with tamoxifen-associated AUB, evaluation is prudent. In contrast, for women who use tamoxifen but who do not have AUB, *screening* with TVS or EMB provides no endometrial cancer-lowering advantage and is not recommended (American College of Obstetricians and Gynecologists, 2017c).

Anticoagulants

The use of anticoagulants confers a risk of HMB or intermenstrual bleeding. The vitamin K antagonists are warfarin and heparin, and the direct oral anticoagulants (DOACs) include apixaban, rivaroxaban, dabigatran, and edoxaban. During AUB evaluation, patients are queried regarding recent dosing changes or antagonist medications. In addition, a prothrombin time (PT), partial thromboplastin time (PTT), and platelet count are usually obtained as bleeding may be related to excess anticoagulant activity.

Management of *chronic* anticoagulant-related AUB can be challenging. If anticoagulant levels lie in therapeutic range, an LNG-IUS, DMPA, or an oral daily progestin is an appropriate option for this indication (Culwell, 2009). Tranexamic acid is contraindicated due to theoretic risks of venous thromboembolism in this population (p. 195). Similarly, the US Medical Eligibility Criteria consider COCs to have risks that outweigh benefits in this setting (Curtis, 2016a). However, a few, including the International Society on Thrombosis and Haemostasis, consider COC use suitable for well-selected and compliant anticoagulated women with AUB (Baglin, 2012; Martinelli, 2016). If a surgical approach is ultimately desired, endometrial ablation or hysterectomy can be considered. Anticoagulation reversal for surgery differs depending on whether surgery is urgent or elective, and both instances are described in Chapter 39 (p. 828).

For acute severe HMB, anticoagulation is reversed. As a temporizing step, a Foley balloon can be inserted into the intrauterine cavity and inflated to tamponade bleeding. Foley balloon sizes range from the traditional 30 mL up to 80 mL, and selection can be tailored to endometrial cavity volume. For a typical uterus, intrauterine tamponade with a 30-mL balloon filled with saline is suitable. Also, the progestins in the table on page 195 can be used. No data describe the safety or risk of short-term, high-dose estrogens or of tranexamic acid in these cases. Surgery or uterine artery embolization (UAE) is associated with higher rates of intra- and postoperative bleeding or thromboembolic complications.

SYSTEMIC CAUSES

Kidney, Liver, and Thyroid Disease

Severe *renal dysfunction* often is accompanied by endocrine disturbances that can lead to AUB. This results from either hypoestrogenism or normal estrogen levels but anovulation (Cochrane, 1997; Matuszkiewicz-Rowińska, 2004). Of additional concern, bleeding may worsen the chronic anemia already associated with renal failure.

For AUB from anovulation, renal patients are treated with traditional methods outlined on page 196 (Guglielmi, 2013). Of specific options, COCs may be contraindicated with severe hypertension or with some systemic lupus erythematosus cases, both of which can complicate renal disease. Moreover, in those with renal disease, NSAIDs are avoided because they cause renal artery vasoconstriction to diminish glomerular function. If women with renal failure and HMB cannot take or do not respond to medical therapy, surgical treatments are considered. Of these, Jeong and coworkers (2004) noted

decreased bleeding in 87 percent of 62 patients following endometrial ablation.

For women with renal disease and with bleeding attributed to estrogen-deficient atrophy, short-term estrogen use is suitable. However, guidelines and robust support for long-term estrogen replacement therapy (ERT) in this population are lacking. If considered, nonoral routes bypass the liver and theoretically may minimize blood pressure elevation. Thrombogenic effects and specifically dialysis-access thrombosis are also a concern (Ahmed, 2017). Last, significantly higher serum estrogen levels with ERT are found in women with advanced renal disease compared with healthy women. Thus, lowest doses and monitoring estrogen levels are reasonable (Mattix, 2000).

Liver dysfunction, depending on its severity, can lead to menstrual abnormalities (Stellon, 1986). The underlying mechanism for bleeding is not clear, but as in renal failure, HPO axis dysfunction is suggested. Additionally, hyperestrogenism from disrupted metabolism can lead to a disordered proliferative or hyperplastic endometrium (de Costa, 1992). Hemostatic dysfunction from poor coagulation factor synthesis may also contribute. Moreover, thrombocytopenia is common in women with portal hypertension and splenomegaly.

Evidence directing HMB treatment in women with liver disease is limited, and hormonal therapy may be inappropriate for some. In those with chronic viral hepatitis and normal transaminase levels or with mild compensated cirrhosis, hormonal contraceptive use is not restricted. In those with active hepatitis or a flare of their chronic viral disease, progestin-only contraception is acceptable. Estrogen-containing products, if already in use, may be continued, whereas initiation of these is avoided. In those with severe, decompensated cirrhosis, all hormonal contraception is avoided (Kapp, 2009). As one surgical option, endometrial ablation was effective and well tolerated in one small study of cirrhotic women (Liu, 2016).

Following liver or renal transplant, women may still be at risk for abnormal bleeding, and a few case series have shown higher rates of endometrial hyperplasia without atypia in transplant recipients with AUB (Bobrowska, 2006; Tohma, 2018).

Both *hyperthyroidism* and *hypothyroidism* can cause menstrual disturbances ranging from amenorrhea to HMB. In many women, these menstrual abnormalities antedate other clinical findings of thyroid disease (Joshi, 1993). Thus, in most women with chronic AUB, serum thyroid-stimulating hormone (TSH) level measurement is recommended. With hyperthyroidism, light or infrequent menses are more typical complaints (Krassas, 2010). With severe overt hypothyroidism, women commonly present with amenorrhea or anovulatory AUB (p. 194). These women can also display defects in hemostasis. This may be due to decreased coagulation factor levels, which have been identified in some hypothyroid patients. With either hypo- or hyperthyroidism, treatment of the underlying thyroid disorder usually corrects AUB (Krassas, 1999; Wilansky, 1989).

Coagulopathy

Normally, a clot forms from an aggregation of platelets, which is then stabilized by a fibrin net. Thus, many coagulation defects leading to HMB can be broadly categorized as either: (1) dysfunction of platelet adherence or (2) defects in platelet plug stabilization. First, during initial stages of hemostasis, platelets adhere to vessel wall breaks through binding of their receptors to exposed collagen. This bridging is dependent on von Willebrand factor, a plasma protein. Once bound, platelets are activated and release a potent agonist of their aggregation, thromboxane. Thus, low platelet number, defects in von Willebrand factor quality or quantity, platelet receptor defects, or thromboxane inhibitors may all lead to poor platelet adherence and HMB. Second, the coagulation cascade leads to fibrin, which stabilizes aggregated platelets. Thus, defects in the clotting factors that comprise this cascade may also predispose to AUB.

In general, coagulopathies are infrequent causes of gynecologic bleeding. However, in the subset of women with HMB and normal anatomy, the incidence is significantly higher (Eising, 2018; Philipp, 2005). This is especially true with adolescents presenting with AUB (Seravalli, 2013). In women with known inherited bleeding disorders, HMB is the most common complaint (Ragni, 2016).

For diagnosis, a history of easy bruising, bleeding complications with surgery or obstetric delivery, recurrent hemorrhagic ovarian cysts, epistaxis, and gastrointestinal bleeding or a family history of bleeding disorders raises concern for coagulopathy. Laboratory screening includes a CBC with platelets, PT, PTT, and fibrinogen level (American College of Obstetricians and Gynecologists, 2017d). More frequently identified coagulopathy disorders are von Willebrand disease, thrombocytopenia, and platelet dysfunction. Specific screening for each is discussed in subsequent sections.

Uncommon reasons include deficiencies of factor VIII and IX (hemophilia A and B) and other factor deficiencies. Acute treatment of these rare disorders is by factor replacement, and long-term management is similar to von Willebrand disease (vWD) (Mannucci, 2004).

Von Willebrand Disease

Von Willebrand factor (vWF) is a glycoprotein synthesized in endothelial cells and in megakaryocytes, which produce platelets. For coagulation, it is integral to platelet adherence at sites of endothelial injury and also prevents clearance of factor VIII. VWD is an inherited bleeding disorder that has several variants, which are characterized by either diminished amount or decreased function of vWF (Table 8-3). In general, type 3 vWD displays autosomal recessive transmission, whereas type 1 and most subtypes of type 2 show an autosomal dominant pattern.

The disorder is most common in Caucasians, and the prevalence of vWD approximates 1 percent in the general population (Rodeghiero, 2001). In screening for coagulopathy, women with vWD may display a prolonged PTT or may have normal results. If vWD is suspected clinically, specific tests include measurement of von Willebrand-ristocetin cofactor activity, vWF antigen concentration, and factor VIII activity (James, 2009b). Of note, factor VIII and vWF levels reach a nadir during menses and are relatively increased in women using COCs. However, testing need not be rescheduled nor COCs halted to complete patient evaluation (James, 2009a). Consultation with a hematologist is often recommended because the diagnosis of vWD, especially in its mild form, can be difficult.

TABLE 8-3. vWD Classification and Laboratory Values

Condition	Description of vWF Deficiency	Bleeding Propensity	vWf:RCo (IU/dL)	vWf:Ag (IU/dL)	FVIII Activity
Type 1	Quantitative: partial	Mild to Moderate	<30	<30	↓ or Normal
Type 2	Qualitative	Moderate	<30	<30–200	↓ or Normal
Type 3	Quantitative: virtually complete	High	<3	<3	↓↓↓(<10 IU/dL)
Normal			50–200	50–200	Normal

FVIII = coagulation factor VIII; vWD = von Willebrand disease; vWF = von Willebrand factor; vWF:Ag = von Willebrand factor antigen; vWF:RCo = von Willebrand factor: risocetin cofactor activity.
From Nichols, 2008, 2009.

Treatments for women with vWD and chronic HMB mirror that for primary endometrial dysfunction (p. 196) (Adeyemi-Fowode, 2017; Foster, 1995; Kingman, 2004). Importantly, agents that prevent platelet adhesion, such as aspirin or NSAIDs, are avoided (American College of Obstetricians and Gynecologists, 2017d).

For women with chronic HMB who do not respond to conventional treatment, a hematologist may be consulted for desmopressin or vWF concentrate use (Nichols, 2008). Desmopressin is a vasopressin analogue that promotes release of vWF from endothelial cells. In those with chronic HMB in whom desmopressin is ineffective or contraindicated, a vWF concentrate can be chosen (Holm, 2015).

In those with vWD-related chronic HMB and no longer desiring fertility, surgical intervention may be considered. Endometrial ablation offers preliminary improvement for affected women. However, it provides less long-term success than for those without a bleeding disorder (Rubin, 2004). Hysterectomy is curative, although rates of bleeding complications from hysterectomy in women with vWD are higher than those of unaffected women (James, 2009c). In preparation for surgical procedures, a hematologist can assist with desmopressin or vWF concentrate dosing.

For severe emergent bleeding, hormonal and antifibrinolytic options shown on page 195 are implemented while clotting factor deficiencies are corrected. In addition, desmopressin can be administered (Edlund, 2002). However, desmopressin is a potent antidiuretic agent. Thus, if multiple doses or shorter dosing intervals are used, then concurrent fluid restriction and monitoring for hyponatremia is advised (Rodeghiero, 2008). Additionally, if aggressive fluid resuscitation is needed, desmopressin may not be appropriate. In this case, vWF concentrates are used instead to quickly raise factor levels (James, 2011). Comprehensive management guidelines for vWD are also available from The National Heart, Lung, and Blood Institute at: http://www.nhlbi.nih.gov/files/docs/guidelines/vwd.pdf.

Platelets

Thrombocytopenia may be broadly categorized as resulting from: (1) increased platelet destruction, as with idiopathic thrombocytopenic purpura (ITP), (2) decreased platelet production, as with hematopoietic malignancy, or (3) increased platelet sequestration, as with splenomegaly.

Alternatively, normal platelet counts may be found, but *platelet dysfunction* leads to poor aggregation. One example is prolonged use of thromboxane inhibitors such as NSAIDs and aspirin. These drugs are often taken by women with AUB due to its close association with dysmenorrhea. Much less often, primary genetic defects in platelet receptors, such Bernard-Soulier syndrome and Glanzmann thrombasthenia, lead to platelet dysfunction and abnormal bleeding.

As a group, evidenced-based data directing the treatment of platelet-associated HMB are limited. For acute, severe HMB, platelet transfusion is considered for counts <20,000/μL or <50,000/μL with brisk bleeding. For those undergoing procedures, a transfusion threshold of ≤50,000/μL is often used, and for major surgery, ≤100,000/μL (James, 2011). Concurrently, treatment is tailored to the underlying cause of thrombocytopenia. Long-term, with the exception of NSAIDs, treatment options include those described later for AUB due to primary endometrial dysfunction (p. 196).

OVULATORY DISORDERS

A large percentage of women with AUB have anovulation as the underlying etiology, and the term AUB-O denotes the ovulatory dysfunction. The underlying causes of anovulation are varied and fully described in Chapter 17 (p. 371). Regardless of the reason, if ovulation does not occur, no progesterone is produced, and a proliferative endometrium persists. For this reason, women with AUB-O are at risk for developing endometrial hyperplasia, EIN, or endometrial cancer.

With AUB-O, bleeding episodes are variable, and classically, several months of amenorrhea are followed by HMB. Management of acute severe bleeding is described in the next section. For chronic management, correction of the underlying cause of anovulation is primary. If this is not possible, chronic progestin therapy replaces the physiologic progesterone that is absent. For women requiring contraception, COCs, progestin-only contraceptive pills, DMPA, LNG-IUS, and etonogestrel subdermal implant are options. In those not desiring contraception, cyclic monthly progesterone followed by withdrawal will typically regulate menses. Suitable oral daily doses given for 10 days each month include: (1) MPA [Provera], 5 or 10 mg; (2) norethindrone acetate (NETA [Aygestin]), 5 or 10 mg; or

(3) micronized progesterone, 300 mg (de Lignières, 1999; Munro, 2000). Another less frequently used choice is a gonadotropin-releasing hormone (GnRH) agonist, which creates profound hypogonadism (Chap. 9, p. 207). The induced amenorrhea can be advantageous to permit severely anemic women with HMB to rebuild their red cell volume.

Surgery is rarely indicated for AUB-O, unless medical therapy fails, is contraindicated, or is not tolerated by the patient. Surgery may also be indicated if the patient has significant concomitant intracavitary lesions. In general, surgical options mirror those for abnormal bleeding associated with primary endometrial dysfunction (p. 197). However, special consideration is given to whether endometrial ablation should be used as first-line therapy for AUB-O. Namely, endometrial ablation is an effective treatment for AUB, but may cause broad intracavitary scar bands, termed synechiae. Acting as an obstruction, these may hinder subsequent satisfactory evaluation of the endometrium in those with AUB-O, who carry higher risks for endometrial hyperplasia, EIN, and cancer (American College of Obstetricians and Gynecologists, 2018b).

PRIMARY ENDOMETRIAL DYSFUNCTION

Unlike the clear mechanism underlying AUB-O, abnormal uterine bleeding from primary endometrial dysfunction (AUB-E) has no clear diagnostic features, and currently this is a diagnosis of exclusion. Suggested mechanisms include dysregulation of local endometrial hemostasis or deficiencies in endometrial repair. The resultant bleeding patterns may be HMB, intermenstrual bleeding, or prolonged bleeding.

Acute Hemorrhage Management

At times, women with AUB may have brisk bleeding that requires acute intervention. Fluid resuscitation is instituted as described in Chapter 40 (p. 862). Medical treatment is simultaneously administered to slow bleeding (Table 8-4). With any of these medication regimens, an intrauterine Foley balloon can be inflated concurrently to control brisk bleeding (p. 192).

As primary choices, equine estrogens can be given intravenously in 25-mg doses every 4 hours for up to three doses (DeVore, 1982). Once bleeding has slowed, patients can be transitioned to an oral taper using Premarin pills or more commonly COCs. These pill forms can also be selected primarily for less severe bleeding. With any of these high-dose choices, an antiemetic may be needed to control estrogen-related nausea. For COC administration, formulations containing at least 30 μg of ethinyl estradiol are selected (Table 5-6, p. 121). If bleeding is significant, the regimen begins with one pill every 6 hours until the bleeding has markedly diminished. For most women, bleeding will slow within 24 to 48 hours. After bleeding has ebbed, the COC dosage is decreased to one pill every 8 hours for the next 2 to 7 days and then to one pill every 12 hours for 2 to 7 days (James, 2011). Subsequently, once-daily dosing is continued for several weeks and then stopped to allow withdrawal menses. This type of dose-diminishing regimen is colloquially known as a "COC taper." This regimen is often individualized to the degree of patient bleeding and may include less frequent dosing or smaller doses. Following this taper, COCs may be discontinued or prescribed long-term for cycle control (Munro, 2006).

TABLE 8-4. Medical Treatment of Acute Severe AUB[a,b]

CEE[c,d]	25 mg IV every 4 hr, up to 3 doses
CEE[d,e]	2.5 mg every 6 hr
COCs[d,e] 30–50 μg	1 pill every 6 or 8 hr, up to 7 d
MPA[e]	10 mg every 4 hr
NETA[e]	5–10 mg every 4 hr
TXA[c]	10 mg/kg IV every 8 hr
TXA	1.3 g every 8 hr for 5 d

[a]Agents given orally except where noted as IV.
[b]For anemic patients, initiate oral iron supplements.
[c]If IV forms required, transition patients to oral agents once bleeding controlled.
[d]Antiemetics may aid nausea.
[e]Oral hormonal agent dosages are tapered by extending dosing from every 6 hr, to every 8 hr, to every 12 hr, and finally to daily. Each new dosing lasts 2 to 7 days depending on the level of concern for rebleeding.
AUB = abnormal uterine bleeding; CEE = conjugated equine estrogen (Premarin); COCs = combination oral contraceptive pills; d = day; hr = hour; IV = intravenous; MPA = medroxyprogesterone acetate; NETA = norethindrone acetate; TXA = tranexamic acid.
From DeVore, 1982; Munro, 2006; James, 2011.

As an alternative to high-dose estrogen therapy for acute HMB, high-dose MPA (10 mg) or NETA (5 to 10 mg) can be used and administered orally every 4 hours. As with oral COCs, dosing is then tapered once bleeding has waned. One proposed taper stretches dosing to every 6 hours for 4 days, then every 8 hours for 3 days, then every 12 hours for 2 to 14 days. The progestin is then continued daily (James, 2011). Another primary regimen uses DMPA 150 mg intramuscularly and combines it with MPA 20 mg orally three times daily for 3 days. Here, the single depot injection serves as the taper (Ammerman, 2013).

Tranexamic acid (TXA) is also an option for acute HMB. This antifibrinolytic drug reversibly blocks lysine binding sites on plasminogen, thus allowing blood clots to persist to slow bleeding (Fig. 8-12). The usual IV dose is 10 mg/kg (maximum 600 mg/dose) every 8 hours. As bleeding declines or for less severe acute bleeding, oral TXA can be given in a dosage of 1.3 g (two tablets) three times daily (James, 2011). The drug has no effect on other blood coagulation parameters such as platelet count, PTT, and PT (Wellington, 2003). Contraindications are concurrent COC use, active thromboembolism, or history of or an intrinsic risk for thromboembolism.

Levonorgestrel-Releasing Intrauterine System

Chronic medical options for AUB-E include LNG-IUS, COCs, sustained progestins, TXA, NSAIDs, androgens, and GnRH agonists (Table 8-5). Of these, the LNG-IUS provides sustained progestin levels within the uterine cavity to atrophy the endometrium. It reduces menstrual loss by 74 to 97 percent

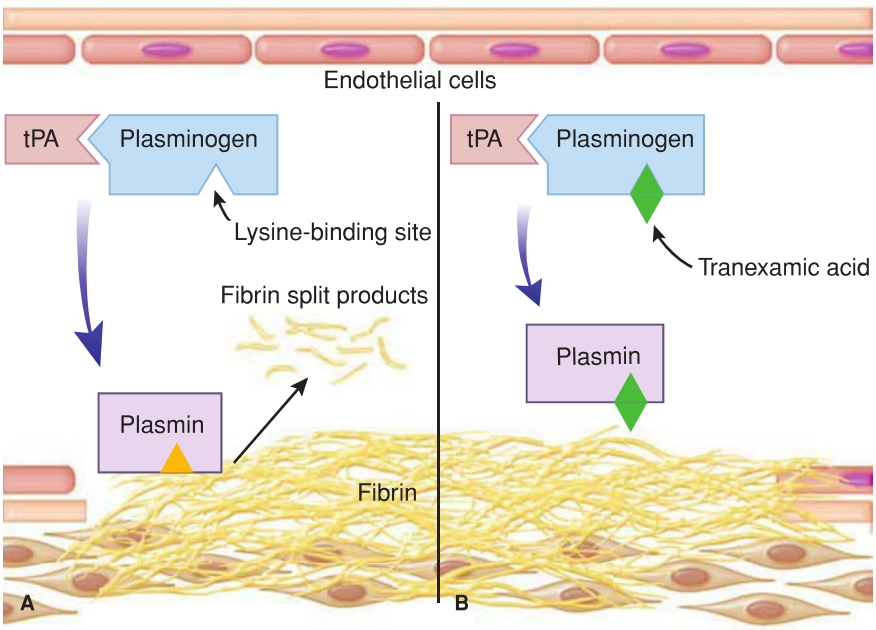

FIGURE 8-12 Tranexamic acid (TXA) mechanism of action. **A.** Normally, plasminogen binds with tissue plasminogen activator (tPA) to form plasmin. This binding degrades fibrin into fibrin degradation products and leads to clot lysis. **B.** TXA binds to the lysine-binding site on plasminogen. This new conformation blocks plasmin binding to fibrin. Fibrin strands are not broken, and a clot persists to slow bleeding.

after 3 months' use (Singh, 2005; Stewart, 2001). The LNG-IUS can be used in most women, including adolescents, as a first-line treatment for HMB. It is particularly useful for reproductive-aged women with AUB who wish to retain fertility. Contraindications are listed in Table 5-4 (p. 115).

In randomized trials of AUB-E, the LNG-IUS proved more effective in decreasing menstrual blood loss than NSAIDs given during menses; than oral progesterone given 21 days each cycle; or than COCs (Irvine, 1998; Reid, 2005; Shaaban, 2011). Other clinical trials have evaluated HMB more generally, bundling several AUB etiologies, including AUB-E. Gupta and coworkers (2013) noted higher associated quality-of-life scores with LNG-IUS compared with several traditional oral medical options. If compared with endometrial ablation, the LNG-IUS appears to have similar therapeutic effects for HMB in women followed 2 years after treatment (Kaunitz, 2009). One randomized trial compared LNG-IUS or hysterectomy for HMB and reported equal improvements in health status and quality of life at 1 year and again after 5 years (Hurskainen, 2001, 2004). However, by 5 years, 42 percent of those assigned to the LNG-IUS eventually underwent hysterectomy, and by 10 years, 46 percent (Heliövaara-Peippo, 2013).

Combination Oral Contraceptive Pills

These hormonal agents effectively treat AUB-E, and when used long term, menstrual blood loss is reduced by 40 to 70 percent (Jensen, 2011; Fraser, 1991, 2011b). Advantages to COCs include the additional benefits of reducing dysmenorrhea and

TABLE 8-5. Chronic Medical Treatment of AUB due to Primary Endometrial Dysfunction[a,b]

Agent	Brand	Dosage
LNG-IUS	Mirena	5-yr intrauterine use
COCs	Table 5-6[c]	One pill daily
DMPA	Depo-Provera	150 mg IM every 3 mo
NETA	Aygestin	5 mg, 3 times daily, days 5–26 of cycle
TXA[d]	Lysteda	1.3 g, 3 times daily × 5 d
NSAID[d]		
Mefenamic acid	Ponstel	500 mg, 3 times daily × 5 d
Naproxen	Naprosyn	550 mg on first day, then 275 mg daily
Ibuprofen	Motrin	600 mg, daily throughout menses
Flurbiprofen	Ansaid	100 mg, 2 times daily × 5 d
GnRH agonists	Lupron	3.75 mg, IM each month (up to 6 mo)

[a]All agents are administered orally except high-dose GnRH agonists, DMPA, and LNG-IUS.
[b]For anemic patients, also initiate oral iron supplementation.
[c]See Table 5-6, p. 121.
[d]Begin treatment with menses onset.
AUB = abnormal uterine bleeding; COCs = combination oral contraceptive pills; DMPA = depot medroxyprogesterone acetate; GnRH = gonadotropin-releasing hormone; IM = intramuscularly; LNG-IUS = levonorgestrel-releasing intrauterine system; NETA = norethindrone acetate; NSAID = nonsteroidal antiinflammatory drug; TXA = tranexamic acid.

providing contraception. Their presumed method of action is endometrial atrophy, although diminished prostaglandin synthesis and decreased endometrial fibrinolysis are other suggested actions (Irvine, 1999).

Tranexamic Acid

In women with AUB-E, fibrinolytic activity within the endometrium is increased compared with that of women with normal menses (Gleeson, 1994). Clinically, the antifibrinolytic effect of TXA reduces chronic bleeding in women with AUB-E by 40 to 50 percent (Bonnar, 1996; Lukes, 2010). In addition, it requires administration only during menstruation and has few minor reported side effects. The recommended dose is two 650-mg tablets orally taken three times daily for a maximum of 5 days during menses. Although used in other parts of the world for many years, oral TXA (Lysteda) was approved by the U.S. Food and Drug Administration (FDA) to treat HMB in 2009.

Nonsteroidal Antiinflammatory Drugs

These well-tolerated oral agents are commonly used to treat AUB-E, and rationale for their use stems from prostaglandin's suspected role in the pathogenesis of this endometrial dysfunction. Because women lose 90 percent of menstrual blood volume during the first 3 days of menses, NSAIDs are most effective if initiated just prior to or with menses onset and continued throughout its duration (Haynes, 1977). Thus, one advantage is that they are taken only during menstruation. Another advantage is that frequently associated dysmenorrhea also improves with NSAIDs.

So-called conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1), an enzyme critical to normal platelet function, and cyclooxygenase-1 (COX-2), which mediates inflammatory response mechanisms. Thus, conventional NSAIDs such as ibuprofen and naproxen may not be ideal considering their inhibitory effects on platelet function. However, no data show an advantage with specific COX-2 inhibitors for HMB compared with conventional NSAIDs. Moreover, among conventional NSAIDS, one is not clinically superior to another, but responses to a particular agent may vary among individuals.

Although NSAIDs require only temporal dosing, are cost-effective, and are well tolerated, they often are only moderately effective for AUB-E and reduce menstrual bleeding by approximately 25 percent (Lethaby, 2013a). Thus, if greater reductions in blood loss are needed, other agents in this section may be more beneficial.

Other Agents

In contrast to AUB-O, AUB-E is relatively unresponsive to cyclic administration of oral progestins (Kaunitz, 2010; Preston, 1995). However, women with AUB-E may respond to longer treatment schedules. NETA, 5 mg, or MPA, 10 mg, each given orally three times daily for days 5 to 26 of each menstrual cycle have proved effective (Fraser, 1990; Irvine, 1998). Unfortunately, prolonged use of high-dose progestins is often associated with side effects such as mood changes, weight gain, bloating, headaches, and atherogenic lipid profile changes (Lethaby, 2008). Moreover, patients may find the dosing schedule challenging.

With GnRH agonists, the profound hypoestrogenic state created induces endometrial atrophy and amenorrhea in most women. Side effects include those typical for menopause, and thus associated bone loss precludes long-term use. This family of drugs, however, may be helpful for short-term use by inducing amenorrhea and allowing women to correct their anemia.

Of androgens, danazol creates a hypoestrogenic and hyperandrogenic environment to induce endometrial atrophy. For HMB, suggested dosing is 100 to 200 mg orally daily (Chimbira, 1980). Although effective, this agent has side effects that include weight gain, oily skin, and acne. Thus, some reserve danazol as a second-line drug for short-term use prior to surgery (Bongers, 2004). Another androgen, gestrinone, has mechanisms of action, side effects, and indications for HMB treatment similar to danazol. The recommended treatment dose is 2.5 mg orally twice weekly (Turnbull, 1990). The drug is used in other countries but is not approved for use in the United States.

Last, women with AUB may become anemic, and care typically is directed toward bleeding abatement and oral iron replacement. Anemia is effectively corrected with 150 to 200 mg of elemental iron daily. One common replacement regimen is ferrous sulfate, 325 mg tablet (contains 65 mg elemental iron) three times daily.

Uterine Procedures

For many women, conservative medical management may be unsuccessful or associated with significant side effects. Surgical management of HMB may include procedures to destroy the endometrium or hysterectomy.

Of these, *dilation and curettage* is rarely used for long-term treatment of AUB because its effects are temporary. Occasionally, D & C is performed to quickly remove endometrium and arrest acute, severe HMB refractory to high-dose estrogen administration (American College of Obstetricians and Gynecologists, 2017b). Notably, preprocedural TVS may be prudent as D & C may be ineffective or disadvantageous for women with an already thinned endometrium.

Endometrial resection or ablation attempts to permanently remove and destroy the uterine lining, using laser, radiofrequency, electrical, or thermal energies. Methods are considered first- or second-generation techniques according to when they were introduced into use and their need for concurrent hysteroscopic guidance (Chap. 44, p. 1061).

Several studies that compared first- and second-generation techniques have shown them equally effective to reduce HMB (Lethaby, 2013b). Similarly equivalent efficacy is seen among the various second-generation options (Daniels, 2012). After ablation, 70 to 80 percent of women experience significantly decreased flow, and 15 to 35 percent of these develop amenorrhea (Sharp, 2006). Increasing treatment failures due to endometrial regeneration accrue with time, and by 5 years following ablation, approximately 25 percent required additional surgery, in most cases hysterectomy (Cooper, 2011). However, the risk of reoperation following resection and ablation procedures is balanced by their significantly lower complication rates compared with hysterectomy.

TABLE 8-6. Endometrial Ablation

Contraindications

Pregnancy
Acute pelvic infection
Endometrial hyperplasia, EIN, or genital tract cancer
Desire to preserve fertility
Postmenopausal women
Expectation of amenorrhea
Large or distorted endometrial cavity[b]
Intrauterine device in place
Prior uterine surgery—classical cesarean delivery, transmural myomectomy

Caution

Those at risk for endometrial cancer[a]

[a]Risks include obesity, chronic anovulation, tamoxifen use, unopposed estrogen use, and diabetes mellitus.
[b]Each device has specific cavity-size limitations.
EIN = endometrial intraepithelial neoplasia.

After ablation, uterine cavity anatomy is often distorted by uterine wall agglutination and intracavitary synechiae. This may pose several long-term problems. First, focal hematometra from menstrual blood trapped behind synechiae can cause severe distention and cyclic pain (Chap. 44, p. 1061). Specifically, postablation tubal sterilization syndrome (PATSS) develops from menstrual blood sequestered between synechiae and previously occluded fallopian tubes. Second, because of distorted anatomy, 33 percent of endometrial sampling attempts may be inadequate, and endometrial stripe evaluation by TVS or hysteroscopic examination may be limited (Ahonkallio, 2009). As noted, endometrial ablation is not routinely recommended for patients at high risk for endometrial cancer. Other contraindications are listed in Table 8-6.

UAE is more commonly used to treat chronic HMB from uterine myomas and is described in Chapter 9 (p. 209). Rarely, this intervention may be considered emergently in women with excessive acute, severe HMB who fail conservation measures, especially those who refuse blood products or who have a coagulopathy. However, the latter may preclude femoral or radial artery cannulation, which is requisite for UAE.

Hysterectomy, despite the above measures, ultimately is chosen by more than half of women with HMB within 5 years of their referral to a gynecologist. In at least a third of these, an anatomically normal uterus is removed (Coulter, 1991). Removal of the uterus is the most effective treatment for bleeding, and overall patient satisfaction rates are high. Disadvantages to hysterectomy include more frequent and severe intraoperative and postoperative complications compared with either conservative medical or ablative surgical procedures. The procedure and its complications are discussed in detail in Chapter 43 (p. 956).

LEIOMYOMAS

Pathogenesis

Often simply called myomas, uterine leiomyomas are benign smooth-muscle neoplasms that typically originate from the myometrium. Their prevalence among women is generally cited as 10 to 20 percent, but is as high as 70 to 80 percent in sonographic studies (Baird, 2003; Marshall, 1997).

Grossly, a typical off-white, whorled leiomyoma is autonomous from its surrounding myometrium because of a thin, outer connective tissue layer (Fig. 9-1). This clinically important cleavage plane allows leiomyomas to be easily "shelled" from the uterus during surgery. The blood supply within these tumors is tenuous, and thus ischemia and necrosis develop frequently in myomas. Following necrosis, their smooth muscle is replaced with various degenerative substances. Forms include hyaline, calcific, cystic, myxoid, red, and fatty, and these gross changes should be recognized as normal variants.

Each leiomyoma is derived from a single progenitor myocyte. Following their genesis, uterine leiomyomas are estrogen- and progesterone-sensitive tumors. And, these tumors carry higher densities of both progesterone and estrogen receptors compared with their surrounding myometrium. Progesterone is considered the critical mitogen for uterine leiomyoma growth and development. In turn, estrogen functions to upregulate and maintain progesterone receptors (Ishikawa, 2010).

To help maintain and promote growth, leiomyomas themselves create a local hyperestrogenic environment (Bulun, 1994; Englund, 1998). Also, some conditions provide sustained estrogen exposure that encourages leiomyoma growth. Examples include early menarche, obesity, and polycystic ovarian syndrome (Wise, 2005,2007). Despite this hormonal responsiveness, myoma formation is not induced by combination oral contraceptive (COC) pills (Qin, 2013). And, depot medroxyprogesterone acetate (DMPA) use in young

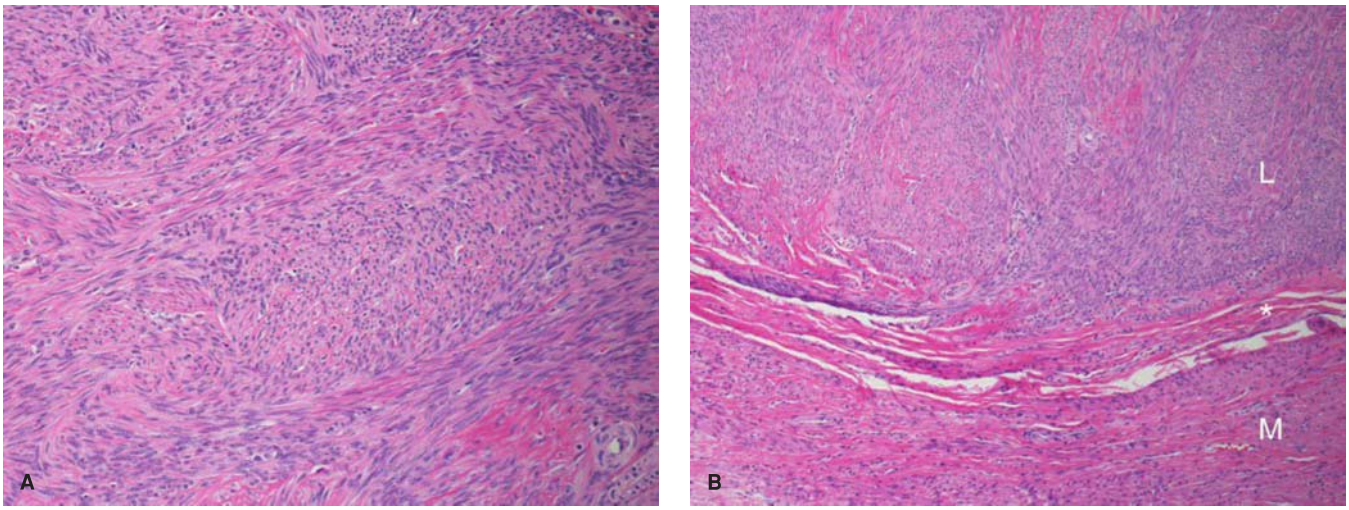

FIGURE 9-1 **A.** Microscopically, leiomyomas are composed of bland, spindled smooth-muscle cells characterized by elongate, blunt-ended nuclei and tapered eosinophilic cytoplasm. The cells are arranged in interlacing fascicles that intersect at right angles. **B.** The interface (*asterisk*) between the leiomyoma (*L*) and adjacent myometrium (*M*) can be seen grossly and microscopically. These tumors are usually more cellular than the surrounding myometrium. (Reproduced with permission from Dr. Kelley Carrick.)

African-American women is associated with lower myoma risk (Harmon, 2015).

For myoma development, race and age are notable factors. Myomas are rare in adolescence, but rates rise with age during the reproductive years. In one study, the cumulative incidence by age 50 years was nearly 70 percent in whites and more than 80 percent in African-American women (Baird, 2003). However, once in the menopause, accruing age lowers the incidence (Sommer, 2015). Leiomyomas are more common in African-American women compared with white, Asian, or Hispanic women (Marshall, 1997). Thus, as noted earlier, heredity and gene mutations play a seminal role in myoma development.

Classification

These tumors are classified numerically based on their location (Fig. 9-2) (Munro, 2018). *Subserosal leiomyomas* originate from myocytes adjacent to the uterine serosa. As variants, *parasitic leiomyomas* attach themselves to nearby pelvic structures from which they derive vascular support. These myomas then may or may not detach from the parent myometrium. *Intramural leiomyomas* are those with growth centered within the uterine walls. *Submucous leiomyomas* are proximate to the endometrium and grow toward and bulge into the endometrial cavity. Last, *pedunculated leiomyomas* attach only by a stalk to their progenitor myometrium. Type 0 and type 7 myomas are examples.

Submucous	4 Intramural
0 Pedunculated intracavity	5 Subserous ≥50% intramural
1 <50% intramural	6 Subserous <50% intramural
2 ≥50% intramural	7 Subserous pedunculated
3 100% intramural but contacts endometrium	8 Other (e.g., cervical, parasitic)

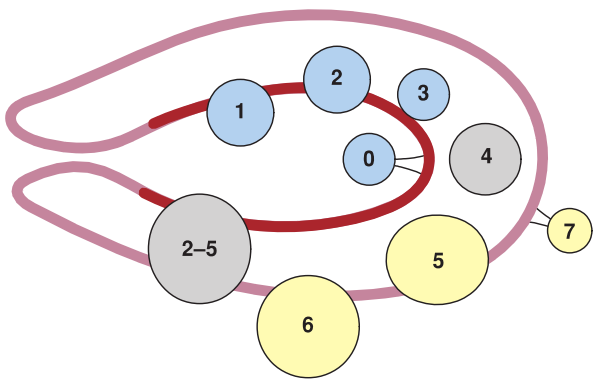

FIGURE 9-2 Leiomyomas categorized by the International Federation of Gynecology and Obstetrics (FIGO) system. Type 3, although completely intramural, is now considered to overlap with the submucous group because of its contact with the endometrium. Not shown, type 8 defines myomas that do not relate to the myometrium and include cervical, broad ligament, or parasitic myomas. Transmural lesions, an example labeled in here as "2-5," are categorized by both their endometrial and serosal components. In these cases, the endometrial surface is described first.

Infrequently, leiomyomas develop in the cervix or broad ligament and rarely in the ovary, fallopian tube, vagina, or vulva.

Symptoms

Bleeding

Most women with leiomyomas are asymptomatic. However, affected women may complain of bleeding, pain, pressure, or infertility. Of these, bleeding is common, especially heavy menstrual bleeding (HMB). Despite this, the underlying pathophysiology is unclear, and vasodilation of endometrial vessels and altered hemostasis are suspected mechanisms (Ikhena, 2018). In general, symptom risk rises with myoma size and number (Baird, 2015).

Pressure and Pain

A sufficiently large uterus can cause chronic pressure, urinary frequency, incontinence, or constipation. Aside from pressure, patients may also note chronic dysmenorrhea, dyspareunia, or noncyclical pelvic pain.

Acute pelvic pain is a less frequent complaint but is most often seen with a degenerating, a prolapsing, or a twisting leiomyoma. With leiomyoma degeneration, tissue necrosis classically causes acute pain, fever, and leukocytosis. This constellation mimics other acute pelvic pain sources. Thus, sonography is typically performed to help identify a cause, and usually a nondescript leiomyoma is found. Computed tomography (CT) may help exclude other etiologies or clarify pelvic anatomy obscured by multiple large leiomyomas. Treatment of myoma degeneration is nonsurgical and includes nonsteroidal antiinflammatory drugs (NSAIDs) and additional analgesics and antipyretics as needed. If differentiation between myoma degeneration and acute endomyometritis is unclear, broad-spectrum antibiotics may be administered. In most cases, symptoms improve within 24 to 48 hours. Also, the stalks of large pedunculated myomas can acutely twist to cause similar ischemia and pain. In this case, surgical severing of the stalk and myoma excision is curative.

Prolapse of a pedunculated tumor from the endometrial cavity can cause marked cramping or pain as the tumor stretches the endocervical canal to pass through it. Associated bleeding or serosanguinous discharge is common. Rarely, cervical stretching may prompt a vagal response or prolapse can lead to uterine inversion. With myoma prolapse, visual inspection is usually diagnostic. However, sonography is often performed to evaluate the size and number of other uterine leiomyomas and exclude other sources of pain. Surgical treatment involves severing the leiomyoma from its stalk as described in Chapter 43 (p. 954).

Fertility Issues

Leiomyomas can diminish fertility, but only 1 to 3 percent of infertility cases are due solely to leiomyomas (Buttram, 1981; Donnez, 2002). Instead, subfertility is more closely associated with submucous leiomyomas than with tumors located elsewhere (American Society for Reproductive Medicine, 2017). Improved pregnancy rates following hysteroscopic resection have provided most of the indirect evidence for this link (Casini,

2006; Surrey, 2005). In contrast, evidence does not implicate subserosal tumors. For intramural leiomyomas that do not distort the endometrial cavity, the relationship with subfertility is more tenuous, and evidence of benefits from myomectomy is conflicting (Christopoulos, 2017; Yan, 2014). Importantly, the strength of this evidence must be weighed against the morbidity associated with myomectomy. Namely, peritubal or intrauterine adhesions can threaten fertility, and myometrial defects lead to a risk of uterine rupture during subsequent pregnancies. If surgery is elected, conception attempts ideally follow complete surgical healing, if possible, to limit tumor recurrence risk.

Both uterine leiomyoma and spontaneous miscarriage are common, and an association between these has not been shown convincingly. Moreover, there is no conclusive evidence that surgical treatment reduces miscarriage rates (American Society for Reproductive Medicine, 2017; Pritts, 2009).

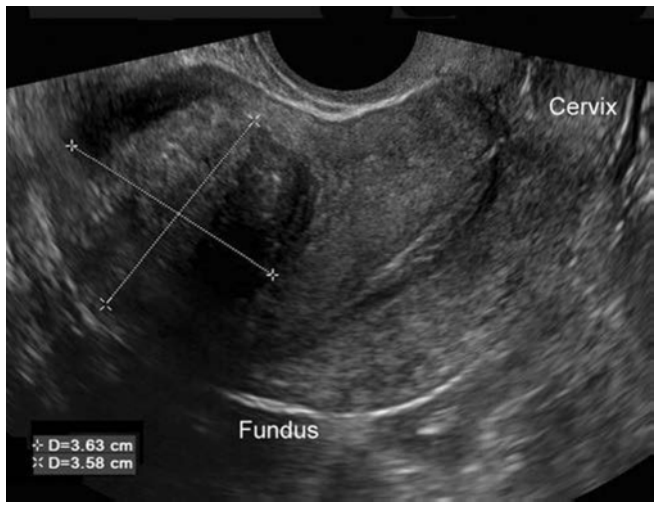

FIGURE 9-3 Transvaginal sonogram of a subserosal leiomyoma. Classically, sonography calipers are placed from outer border to outer border during myoma measurement.

Diagnosis

Leiomyomas are often detected by pelvic examination with findings of uterine enlargement, irregular contour, or both. In reproductive-aged women, a urine or serum β-human chorionic gonadotropin (hCG) level excludes pregnancy, and sonography is done to define pelvic anatomy. Of modalities, transvaginal sonography (TVS) provides superior resolution, but some uteri are so large that transabdominal sonography is needed to image the entire corpus. Leiomyomas appear as focal masses with a heterogeneous texture. This varies from hypo- to hyperechoic depending on the ratio of smooth muscle to connective tissue and the presence of degenerative substances (Fig. 9-3). Calcifications appear hyperechoic and commonly rim the tumor or are randomly scattered throughout the mass. Cystic or myxoid degeneration typically dots the leiomyoma with multiple, smooth-walled, irregularly sized but generally small hypoechoic or anechoic areas.

The endometrial cavity is also inspected for submucous leiomyomas, endometrial polyps, or synechiae. With these focal lesions, the endometrium can appear thick or irregular during TVS, and adjunct imaging tools may help clarify anatomy. Of these, saline-infusion sonography (SIS) or hysteroscopy often best provide additional cavity information (Figs. 9-4 and 9-5). Also, three-dimensional (3-D) TVS and 3-D SIS can be valuable to define the cavity.

Leiomyomas have characteristic vascular patterns, and these can be identified by color Doppler and by power Doppler techniques. A peripheral circumferential rim of vascularity from which a few vessels arise to penetrate into the center of the tumor is a classic finding. Adenomyosis usually shows central rather than peripheral vascularity (Sharma, 2015). Polyps classically show one feeder vessel. As such, Doppler imaging can help differentiate these.

For the infertile woman, the endometrial cavity can be evaluated with hysterosalpingography (HSG), hysterosalpingo-contrast sonography (HyCoSy), or hysteroscopy. The first two also offer the advantage of defining tubal patency.

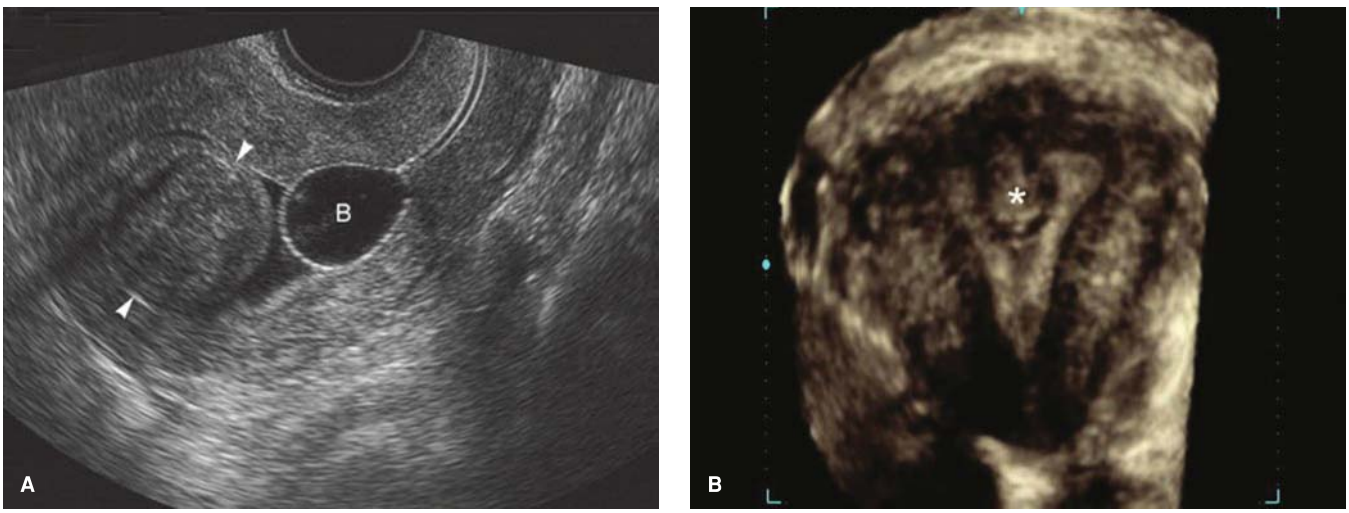

FIGURE 9-4 A. Submucous fibroid is clearly outlined during saline infusion sonography (SIS) (*arrowheads*). The SIS catheter balloon is seen in the lower uterine cavity (*B*). **B.** 3-D transvaginal sonogram of a submucous leiomyoma (*asterisk*). (Reproduced with permission from Dr. Elysia Moschos.)

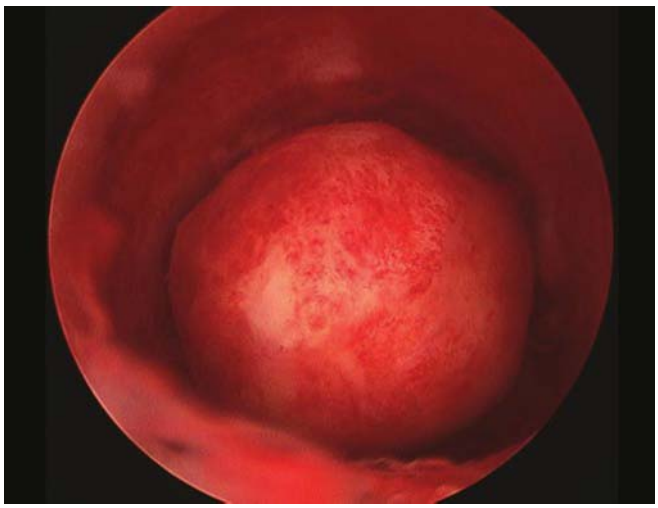

FIGURE 9-5 Hysteroscopic photograph of a submucous leiomyoma prior to resection. (Reproduced with permission from Dr. Karen Bradshaw.)

Magnetic resonance (MR) imaging may be required when imaging is limited by body habitus or distorted anatomy. On T2-weighted images, myomas usually are dark, homogeneous, and circumscribed. Notably, areas of degeneration create variations of this typical appearance. MR imaging allows more accurate assessment of the size, number, and location of leiomyomas. This can help identify appropriate candidates for hysterectomy alternatives such as uterine artery embolization (UAE) or myomectomy. Of note, for a dominant fundal uterine mass, MR imaging can also aid differentiation of a fundal leiomyoma, which is a suitable myomectomy indication, from a compact collection of adenomyosis, which is not. Another mimicker is leiomyosarcoma (LMS), which is often a single, large mass with cystic degeneration. MR imaging provides greater, but not perfect, accuracy for diagnosis of LMS (Bonneau, 2014).

CT is not widely used to further characterize myomas. However, as discussed earlier, it may aid initial diagnosis in patients with acute pain of unclear etiology.

Nonsurgical Management

Observation

Leiomyomas in general are slow-growing (DeWaay, 2002). Thus, regardless of their size, asymptomatic leiomyomas usually can be observed and surveilled with an annual pelvic examination (Parker, 1994). At times, adnexal assessment may be hindered by a large or irregular uterus or patient obesity. In these cases, some add annual sonographic surveillance (Cantuaria, 1998).

In contrast, symptomatic leiomyomas can be treated with long-term medical therapy discussed in the next sections (Table 9-1). In others, medical therapy is used only as a short-term preoperative adjunct. Also, because these tumors typically regress postmenopausally, some women choose medical treatment to relieve symptoms as a bridge to menopause.

Sex Steroid Hormones

Either COCs, continuous oral progestins, or DMPA can be used to induce endometrial atrophy and to decrease prostaglandin production. Despite this frequent practice, few studies have evaluated these specifically for leiomyoma-related bleeding (Kriplani, 2016; Sayed, 2011). Their use and expected effects are extrapolated from studies in women with nonmyomatous uteri.

Also in small studies, the levonorgestrel-releasing intrauterine system (LNG-IUS) significantly improved leiomyoma-related bleeding scores (Sayed, 2011; Socolov, 2011). However, for women with myomas, LNG-IUS expulsion rates are higher and range from 10 to 15 percent (Kriplani, 2012; Youm, 2014). Candidates should meet criteria listed in Table 5-4 (p. 115), and tumors that distort the endometrial cavity preclude LNG-IUS use (Bayer, 2017). Placement into the large cavities of enormous uteri is also avoided, as the device and its strings may migrate cephalad to make retrieval difficult. Although not a strict clinical limit, many studies have included only uteri measuring ≤12-week size.

Other sex steroid hormone options include the androgens danazol and gestrinone, which shrink leiomyoma volume and improve bleeding symptoms (Coutinho, 1989; De Leo, 1999). Unfortunately, their prominent side effects, which include acne and hirsutism, preclude their use as first-line agents.

GnRH Receptor Agents

Synthetic derivatives of gonadotropin-releasing hormone (GnRH) can function at the GnRH receptor as either agonists or antagonists. Despite their differing actions at the receptor, both groups ultimately incite profound systemic drops in estrogen and progesterone levels.

GnRH agonists are inactive if taken orally, but other preparations are available. Of these, leuprolide acetate (Lupron) is Food

TABLE 9-1. Indications for the Medical Treatment of Uterine Leiomyoma

Agent	NSAID	COC	DMPA	LNG-IUS	GnRH Agonist	Ulipristal[a]
Symptom						
Dysmenorrhea	+	+	+	+	+	+
Menorrhagia	–	+	+	+	+	+
Pelvic pressure	–	–	–	–	+	+
Infertility	–	–	–	–	+	–

[a]Available in Europe and Canada for preoperative use for this indication.
COC = combination oral contraceptive pills; DMPA = depot medroxyprogesterone acetate; GnRH = gonadotropin-releasing hormone; LNG-IUS = levonorgestrel-releasing intrauterine system; NSAID = nonsteroidal antiinflammatory drug.

and Drug Administration (FDA)-approved for leiomyoma treatment and is available in a 3.75-mg monthly dose or 11.25-mg 3-month intramuscular (IM) dose. Less frequently used GnRH agonists include goserelin (Zoladex), administered as a 3.6-mg monthly or 10.8-mg 3-month subcutaneous depot implant. Triptorelin (Trelstar) is given as a 3.75-mg monthly or 11.25-mg 3-month IM injection. Nafarelin (Synarel) is used in a 200-μg twice-daily nasal spray regimen. These latter three are not FDA-approved for leiomyoma treatment, but in off-label use they have proved effective (Donnez, 2003; Vercellini, 1998).

GnRH agonists shrink leiomyomas by targeting the growth effects of estrogen and progesterone. Initially, these agonists stimulate receptors on pituitary gonadotropes to cause a supraphysiological release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Also called a *flare*, this phase typically lasts 1 week. With their long-term action, however, agonists downregulate GnRH receptors in gonadotropes, thus desensitizing gonadotropes to further GnRH stimulation. Subsequently, lowered gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration (Broekmans, 1996).

Results with GnRH agonist treatment include dramatic decreases in uterine and leiomyoma volume. Most women experience a mean decline in uterine volume of 35 to 50 percent, and most of this occurs during the first 3 months of therapy (Donnez, 2012b; Friedman, 1991). As a result, smaller uterine size may allow a less complicated or extensive surgical procedure.

Clinical benefits of GnRH agonists include pain relief and diminished HMB, usually amenorrhea. For example, 90 to 97 percent of women achieve bleeding control by 3 months. The mean time to amenorrhea is 21 days (Donnez, 2012b; Friedman, 1991). Adjunctively, women can be given oral iron supplements to correct anemia.

Following their discontinuance, normal menses resume in 1 to 2 months (Letterie, 1989). Unfortunately, leiomyomas then regrow, and uterine volumes regain pretreatment sizes within 3 to 6 months (Friedman, 1991). Despite regrowth, symptom relief may persist for 6 to 12 months in many women given GnRH agonists (Scialli, 2000; Schlaff, 1989).

GnRH agonists have significant costs and side effects. Side effects mirror those of menopause and develop in up to 95 percent of treated women (Letterie, 1989). In addition, 6 months of agonist therapy can result in a 6-percent loss in trabecular bone, not all of which may be recouped following discontinuation (Scharla, 1990). As a result, these agents alone are not recommended for use longer than 6 months without add-back therapy.

To obviate side-effect severity, "add-back therapy" counters hypoestrogenic symptoms without negating the shrinking action (Friedman, 1994). This is made possible by the fact that the estrogen level required to improve vasomotor symptoms and minimize bone loss is below the estrogen threshold that would restimulate leiomyoma growth. Add-back therapy is typically begun 1 to 3 months following GnRH agonist initiation (Mizutani, 1998). Regimens include estrogen combined with a progestin, and those studied have generally been low-dose preparations equivalent to menopausal HRT. Of note, progestins, such as norethindrone or medroxyprogesterone acetate, as a sole agent for add-back therapy have yielded contradictory results (Carr, 1993; Friedman, 1994). Last, although used less often, add-back therapy with selective estrogen-receptor modulators (SERMs), such as tibolone and raloxifene, also prevents bone loss (Palomba, 1998, 2004).

GnRH antagonists, elagolix and relugolix, are nonpeptide forms suitable for oral use, although not yet FDA-approved for this indication. As one advantage, the initial flare of gonadotropins is avoided. In randomized trials, both menstrual bleeding and myoma volumes declined (Archer, 2017; Carr, 2018; Osuga, 2019). As expected with GnRH suppression, hot flashes are a prominent side effect. However, add-back therapy attenuates both hot-flash severity and bone mineral density losses during 6 months of treatment. Yet, diminished menstrual blood loss is preserved.

Selective Progesterone-Receptor Modulators

As noted, progesterone is essential for myoma growth, and thus antagonists are another option. Agents are classified as *antiprogestins* if they universally prompt antagonist effects upon binding to the progesterone receptor. However, agents are termed *selective progesterone-receptor modulators (SPRMs)* if they exert antiprogestational effects in some tissues but progestational effects in others.

Ulipristal acetate (UPA) is an SPRM currently marketed in the United States as the emergency contraceptive Ella. For myoma treatment, UPA is available in Europe and Canada (Esmya, Fibristal) and prescribed in 5-mg oral daily doses for up to 12 weeks. UPA acts as a potent antiprogestin in myomas and shrinks their volume. UPA performs comparably with leuprolide acetate to shrink myoma volume and controlled heavy menstrual bleeding (Donnez, 2012b). But unlike GnRH-receptor agents, it avoids the gonadotropin flare and hypoestrogenic side effects. Estradiol levels lie in the midfollicular range (Donnez, 2016).

The effect of UPA on the endometrium is not that of a pure antagonist. Instead, a new category of endometrial changes are recognized with UPA use. These *progesterone-receptor-modulator–associated endometrial changes (PAECs)* reflect dyssynchronous growth between glands and stroma (Mutter, 2008). PAECs are not linked to short-term higher rates of endometrial hyperplasia or cancer. And, in the largest randomized studies of UPA, PAECs revert within 3 to 6 months following drug cessation (Donnez, 2012a,b). However, the long-term effects of PAECs are unclear, and this is the main reason that each treatment course is limited to 12 weeks. That said, repetitive courses of UPA have been evaluated (Donnez, 2016).

More recently, concerns have arisen regarding liver injury, and underlying liver disease is now a contraindication. The European Medicines Agency (2018) still permits one 12-week course preoperatively. Additional courses are allowed only to those who are not eligible for surgery. Serum liver-function testing is done pretreatment, then monthly during the first two 12-week courses, and finally 2 to 4 weeks posttreatment. Enzyme levels three or more times the upper normal limit should prompt treatment cessation.

Nonhormonal Options

Tranexamic acid (TXA) is an antifibrinolytic agent described fully in Chapter 8 (p. 196). Studies have not evaluated TXA specifically for myoma-related HMB. Subgroup analysis does provide some support for its use for this indication (Eder, 2013; Lukes, 2010).

The benefits of NSAIDs for leiomyoma-related bleeding are less clear, and studies have conflicting results (Anteby, 1985; Mäkäräinen, 1986). Thus, although NSAIDs are potentially helpful for myoma-related dysmenorrhea, available data do not robustly support their use as sole agents for leiomyoma-related HMB.

The enzyme aromatase converts androgens to estrogens and is active in the ovary, breast, endometrium, adipose, bone, and endothelium, among others. In myomas, aromatase contributes to the estrogen environment that propels and sustains myoma growth. In premenopausal women, inhibitors of aromatase appear to predominantly suppress estrogen production in myomas yet only partial suppress this activity in the ovary. Aromatase inhibitors (AIs) are not FDA-approved for leiomyoma treatment. But, in a few small studies, they decreased myoma volumes by approximately 50 percent and improved menstrual symptoms during 3-month therapies (Parsanezhad, 2010; Sayyah-Melli, 2017). AI side effects include hot flashes, nausea, and musculoskeletal pain. Moreover, AI use can augment FSH release, which can risk pregnancy or formation of multiple follicular cysts. Long-term effects on bone and cardiovascular health are also unclear. AIs are not widely used, and larger studies are needed.

Uterine Artery Embolization

Uterine artery embolization is an angiographic procedure that delivers synthetic particulate emboli into both uterine arteries. Uterine blood flow is thereby obstructed, producing ischemia and necrosis. Because vessels serving leiomyomas have a larger caliber, these microspheres are preferentially directed to the tumors, sparing the surrounding myometrium.

During UAE, an angiographic catheter is placed in one femoral artery and advanced under fluoroscopic guidance to sequentially catheterize both uterine arteries (Fig. 9-6). Failure to embolize both uterine arteries allows collateral circulation to sustain leiomyoma blood flow and is associated with a significantly lower success rate (Bratby, 2008).

UAE is a management option for women who might otherwise be considered candidates for hysterectomy or myomectomy. Based on current evidence, women who have not completed childbearing may be better served by myomectomy (Gupta, 2014). Other patient limitations are listed in Table 9-2, and many are associated with altered vascular anatomy. For example, GnRH agonists are thought to narrow vessels. Pedunculated submucous tumors are less suitable, as these tumors can infarct and slough. Pedunculated subserosal tumors were previously excluded, but the Society of Interventional Radiology has removed this caveat (Dariushnia, 2014).

Prior to UAE, a woman undergoes radiologic consultation and MR imaging to assess myoma qualities for success. The gynecologist screens for infection and for endometrial and cervical cancer. Before UAE, intrauterine devices are typically removed.

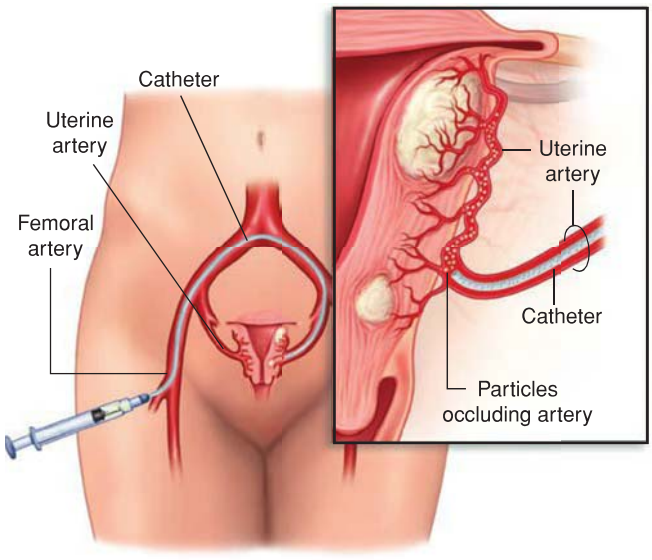

FIGURE 9-6 Diagram of uterine artery embolization (UAE).

Following UAE, pain management usually requires a 24- to 48-hour hospital admission. After discharge, most patients have pain controlled with NSAIDs and have a rapid return to daily activities. However, as a result of leiomyoma necrosis, patients can develop a *postembolization syndrome* that may require readmission. These symptoms are seen in 10 to 25 percent of cases, usually last 2 to 7 days, and are classically marked by pelvic pain, nausea, low-grade fever, and mild leukocytosis (Edwards, 2007; Hehenkamp, 2005,2006). Management includes supportive care and analgesia. Antibiotics are not typically required but may be administered if infectious endomyometritis is an alternative diagnosis.

TABLE 9-2. UAE Absolute and Relative Contraindications

Absolute	
Pregnancy	
Active uterine or adnexal infection	
Suspected reproductive tract malignancy[a]	
Relative	**Reason**
Coagulopathy	Bleeding complications
Renal impairment	Renal effects of contrast
Severe contrast allergy	Allergic reaction
Desire for future fertility	See text
Uterine size >20–24 weeks	Difficult to embolize
Prior salpingectomy or SO	Altered arterial anatomy
Prior pelvic radiation	Altered arterial anatomy
Large hydrosalpinx	Increased infection risk
GnRH agonist use	Narrows vascularity

[a]Unless performed as an adjunct to treatment.
GnRH = gonadotropin-releasing hormone; SO = salpingo-oophorectomy; UAE = uterine artery embolization.
Compiled from American College of Obstetricians and Gynecologists, 2016; Dariushnia, 2014; Stokes, 2010.

Bleeding and bulk relief is not immediate, but by 6 months clinical responses are significant (Moss, 2016). Several trials have shown high rates of patient satisfaction and symptom improvement (Edwards, 2007; Hehenkamp, 2008). Compared with hysterectomy, UAE is associated with shorter hospitalization, reduced 24-hour pain scores, and earlier return to daily activities. UAE also compares favorably with myomectomy for symptom relief (Goodwin, 2006; Manyonda, 2012). However, long-term surveillance reveals that 28 to 35 percent of UAE-treated patients will require a subsequent procedure, which in many cases is hysterectomy (Moss, 2011; de Bruijn, 2016).

Compared with surgery, UAE has comparable major complication rates but higher minor complication rates (Gupta, 2014). Leiomyoma tissue passage is common and seen in approximately 4 percent of cases (Toor, 2012). Necrotic leiomyomas that pass into the vagina usually can be removed in the office. Those retained in the uterine cavity or firmly attached to the uterine wall may require dilatation and evacuation (Spies, 2002). Groin hematoma and prolonged vaginal discharge are other frequent complications. Brief amenorrhea and associated transiently elevated FSH levels may last a few menstrual cycles after UAE. Permanent amenorrhea, however, develops occasionally, and more often in older reproductive-aged patients (Hehenkamp, 2007; Spies, 2005). This likely results from concurrent embolization of the ovaries. Pregnancy subsequent to UAE can pose complications. Although the number of evaluable pregnancies is small, consistent problems include higher rates of miscarriage, postpartum hemorrhage, and cesarean delivery (Homer, 2010).

In sum, UAE has typically low major complication rates and high symptom-relief scores. However, these are balanced against the need for ultimate reintervention in a significant number of women.

Magnetic Resonance–Guided Focused Ultrasound

With MR-guided focused ultrasound (MRgFUS), ultrasound energy is focused to heat and incite coagulative necrosis in selected myomas (Fig. 9-7). Concurrent MR imaging enables this energy to be precisely targeted and also provides real-time tissue temperature feedback to limit surrounding tissue injury. After treatment, gadolinium-enhanced MR images are obtained to measure the *nonperfused volume* within the treated myomas. This correlates positively with tumor and symptom reduction (Park, 2014).

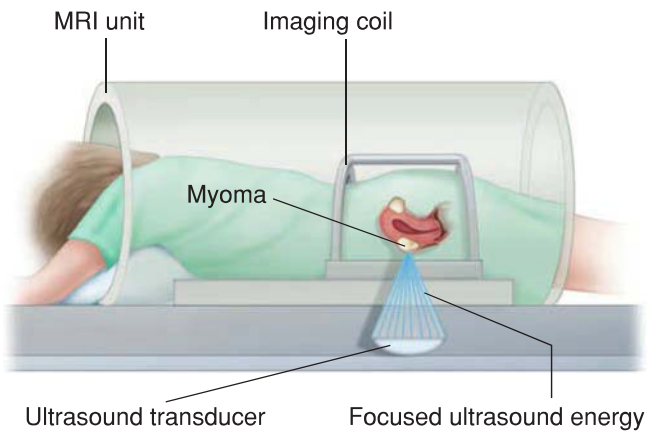

FIGURE 9-7 Diagram of magnetic resonance-guided focused ultrasound.

Also called MR-guided high-intensity focused ultrasound (MR-HIFU), this procedure requires only conscious sedation and is associated with rapid recovery. Sessions last 2 to 3 hours during which a patient lies prone within the MR imaging unit and the bladder is continuously drained.

For potential candidates, manufacturer contraindications are pregnancy, uterine malignancy, menopause, calcified myomas, general contraindications to MR imaging, and obstructions along the energy path. These latter include abdominal wall scars, bowel, or foreign bodies. In studies, other exclusion criteria have been current pelvic infection, uterine size >24 weeks, myoma size >10 cm, and myomas lying deeper than 12 cm from the skin surface (Kim, 2011; Pron, 2015). Also, failure or injury rates are greater with pedunculated serosal or submucous myomas, concurrent adenomyosis, tumors near vital structures, or more than four myomas (Mindjuk, 2015). Because of these limitations, many women are ineligible.

Early prospective studies show that MRgFUS improves quality-of-life scores and is well tolerated (Hindley, 2004). Potential minor complications include vaginal discharge, fever, hematuria, and abdominal wall edema. More serious conditions are venous thromboembolism, necrotic myoma tissue retained in the uterine cavity, heavy uterine bleeding, endometritis, and burns.

MRgFUS with the Exablate device is now permissible for women who desire fertility preservation. In one review of 102 pregnancies following MRgFUS, most of the 48 live births were full term and appropriately sized, 13 percent had antepartum spotting, 4 percent had placenta previa, and 4 percent required manual placenta removal (Keltz, 2017). Placenta accreta or uterine rupture was not noted.

Comparing UAE and MRgFUS, the FIRSTT randomized trial showed a 30-percent reintervention rate within 3 years after MRgFUS. The rate was only 13 percent for UAE (Laughlin-Tommaso, 2019). Other efficacy data are from nonrandomized cohorts that offer relatively short-term results. Improvement in symptoms scores ranges from 30 to 70 percent. But, similar to UAE, symptom relief wanes with time. At ≥12 months following MRgFUS, 13 to 24 percent sought alternative procedures for their symptoms, including hysterectomy (Kim, 2011; Machtinger, 2012; Mindjuk, 2015). Compared with UAE in one small study, MRgFUS was less successful in providing symptom improvement at 5 years, and 67 percent of women elected reintervention (Froeling, 2013).

As an alternative to MR guidance, a newer modality uses ultrasound imaging to focus ultrasound energy but is not yet FDA approved. Also, ultrasound-guided focused ultrasound (USgFUS) does not provide thermal feedback from the myoma. Limited data regarding its efficacy and safety concerns mirror those with MRgFUS (Chen, 2016; Parsons, 2017).

Surgery

Hysterectomy

For women with persistent symptoms despite conservative efforts, hysterectomy, myomectomy, endometrial ablation, and myolysis are options. Of these, hysterectomy is the definitive and

most common surgery. It can be performed vaginally, abdominally, or laparoscopically depending on patient and uterine factors. Symptomatic cervical or broad ligament leiomyomas are best treated with hysterectomy.

Following hysterectomy, postoperative satisfaction rates are high, and data show superior rates compared with conservative options (Carlson, 1994; De Bruijn, 2016). However, benefits are balanced against the risks of major surgery.

Myomectomy

This uterus-preserving surgery excises myomas and is considered for women who desire fertility preservation or who decline hysterectomy. Contraindications are active infection, pregnancy, and suspected malignancy. Compared with hysterectomy, myomectomy poses a higher risk of myoma recurrence and incomplete symptom relief but has lower rates of injury to adjacent organs. Blood loss, surgery length, febrile morbidity, and hospital stays are comparable for surgery performed on uteri up to 16-week size (Iverson, 1996; Sawin, 2000).

Myomectomy can be performed hysteroscopically, laparoscopically, or via laparotomy, and these are illustrated in the atlas portion of this book. In general, predominantly intracavitary myomas are resected hysteroscopically, whereas subserosal or intramural myomas require laparotomy or laparoscopy for surgical excision.

For intracavitary myomas, hysteroscopic resection affords quicker recovery and less surgical morbidity than hysterectomy or laparoscopic myomectomy. The efficacy of hysteroscopic myomectomy positively correlates with percentage of excised volume, and the size, topography, extension, penetration, wall (STEPW) criteria can guide patient selection (Table 9-3) (Tsujioka, 2017). Resection is most effective with type 0 and type 1 tumors and with those measuring ≤3 cm (Mazzon, 2015). Although suitable for skilled surgeons, larger or type 2 myomas carry higher risks for incomplete resection, difficult visualization, uterine perforation, or reaching media volume limits (Arnold, 2016). For hysteroscopic myomectomy in general, 15 to 20 percent of treated women eventually require additional surgery (Emanuel, 1999; Hart, 1999).

In contrast, for women with subserosal or intramural myomas, surgeons must enucleate tumors buried in the muscular uterine walls and then reconstruct normal anatomy. As such, surgical complexity and subsequent risks are increased. This type of myomectomy usually improves pain and bleeding. For example, HMB improves in approximately 70 to 80 percent of patients (Buttram, 1981; Olufowobi, 2004). Reintervention rates are 10 to 15 percent (Hanafi, 2005; Yoo, 2007).

When selecting a surgical approach for subserosal or intramural myomas, several factors are weighed. Laparoscopic leiomyoma resection yields successful outcomes and recurrence rates that are comparable to those for laparotomy (Bhave Chittawar, 2014; Rossetti, 2001). Advantageously, shorter hospital stays and less febrile morbidity, blood loss, adhesion formation, and pain are found with laparoscopic resection (Jin, 2009; Takeuchi, 2002). However, uterine rupture in subsequent pregnancy, although rare, has higher rates following laparoscopic enucleation (Pop, 2018). Single-layer closures and thermal myometrial injury from greater electrosurgery use are proposed causes (Parker, 2010).

Patient selection criteria vary by surgeon, but for a laparoscopic approach limits can include large myoma size (≥6 to 10 cm), many tumors (≥3), and locations that require multiple incisions. In general, large intramural and multiple myomas require greater laparoscopic skill (Juhasz-Böss, 2017).

To overcome some of these limits, minilaparotomy techniques may be elected. However, similar to larger laparotomy incisions, minilaparotomy is faster but still underperforms laparoscopy with regard to patient pain scores, hospital stay, and blood loss (Alessandri, 2006; Palomba, 2007). Also, robot-assisted myomectomy has been described. Overall, this offers similar minimally invasive surgery (MIS) advantages but longer operating times and greater cost (Buckley, 2015). Moreover, due to poor tactile feedback from robotic instruments, myomas may be missed, leading to higher recurrence rates (Griffin, 2013).

In sum, for those considering myomectomy, hysteroscopic resection is preferred when possible. For remaining cases, selection varies depending on myoma characteristics and surgeon skill. MIS, when feasible, offers decreased postoperative pain and surgical complication rates comparable to laparotomy.

TABLE 9-3. STEPW Criteria for Hysteroscopic Myomectomy

	Points			
Criteria	0	1	2	Total
Size (cm)	≤2	>2–5	>5	
Topography	low	middle	upper	
Base width	≤⅓	>⅓–⅔	>⅔	
Penetration	0	≤50%	>50%	
Lateral wall	If along lateral wall, then +1			

Point totals from 0–4 = Group I; from 5–6 = Group II; from 7–9 = Group III. Surgical difficulty increases as point totals rise. Adapted from Wamsteker, 1993; Lasmar, 2005.

Endometrial Ablation

Several endometrium-destructive modalities are often elected for abnormal uterine bleeding due to endometrial dysfunction. These can be also used as a sole technique for myoma-related bleeding. However, data are conflicting as to whether the failure rate is higher in those with myomas (Klebanoff, 2017; Longinotti, 2008). Of note, most of these modalities have limitations regarding cavity length and degree of cavity distortion. That said, some data show efficacy if treating submucous myomas measuring ≤3 cm (Glasser, 2009). However, these specific tumors may be more suited to hysteroscopic resection. Instead, some have used ablation as an adjunct following hysteroscopic leiomyoma resection in women with HMB (Loffer, 2005).

Myolysis and Other Approaches

Myolysis describes procedures using tools that directly contact the myoma to incite myoma necrosis and subsequent shrinkage. With the various procedures, radiofrequency energy, laser vaporization, or cryotherapy ablates the myoma.

Of these, the Acessa system uses a monopolar radiofrequency needle that is inserted transabdominally into each tumor during

laparoscopy. Radiofrequency ablation (RFA) may be best suited for women with myomas <7 cm and uterine sizes <16 weeks. Exclusion criteria from studies have included myomas >10 cm, type 0 or type 1 myomas, pregnancy, infection, suspected malignancy, recent GnRH agonist use, suspected adenomyosis, and prior pelvic radiation. A desire for future fertility is not a contraindication. Data on pregnancy outcomes are few but encouraging (Keltz, 2017).

With this newer approach, early evidence shows a 50-percent improvement in symptom severity scores at 1 year (Chudnoff, 2013). In studies, reintervention rates were 11 percent at 3 years and 29 percent at 5 years (Berman, 2014; Iversen, 2017). Compared with laparoscopic myomectomy, RFA offers shorter operative and recovery times and less blood loss (Brucker, 2014). Short-term outcomes are comparable with those of laparoscopic myomectomy (Berman, 2014).

Different from myolysis, laparoscopic uterine artery occlusion (LUAO) attempts to achieve myoma necrosis by surgically sealing both the ovarian arteries and the uterine arteries near their origin from the internal iliac artery (Ambat, 2009). In studies, the reintervention rate at 16 months was 15 percent, but at 4 years it was 28 percent and similar to UAE (Hald, 2009; Mara, 2012). For now, the required advanced surgical skills and scarce long-term outcome data limit its use.

Rare Manifestations

Most myomas are treated as just described. However, uncommon tumor complications can also affected numerous other organ systems. First, deep-vein thromboembolism risks are increased in those with myomas weighing >1000 g (Shiota, 2011). Of uncommon urologic complications, acute urinary retention may stem from compression by a myoma or by an incarcerated myomatous uterus. As management, bladder drainage by Foley catheter or by intermittent self-catheterization is a temporizing option. In contrast, severe hydronephrosis originates from ureteral compression, usually at the pelvic brim (Alyeshmerni, 2011). Both retention and ureteral obstruction can be resolved with removal or shrinkage of myomas.

Also rarely, *myomatous erythrocytosis syndrome* can create an elevated red blood cell (RBC) count but not the pancytosis that characterizes polycythemia. This syndrome stems from excessive erythropoietin production, most likely by the myoma itself (Ono, 2014). Following hysterectomy, the RBC count returns to normal.

Leiomyomas infrequently may cause *pseudo-Meigs syndrome* (Yonehara, 2014). Traditionally, Meigs syndrome consists of ascites and pleural effusions that accompany a benign ovarian fibroma. However, any pelvic tumor can cause this. If due to a myoma, resolution of ascites and hydrothorax follows hysterectomy or myomectomy.

An autosomal dominant mutation in the *fumarate hydratase (FH)* gene underlies the rare *hereditary leiomyomatosis and renal cell cancer (HLRCC) syndrome*. Also called Reed syndrome, the classic triad is cutaneous and uterine leiomyomas and renal cell cancer (Miettinen, 2016).

Rarely, extrauterine smooth muscle tumors, which are benign yet infiltrative, may develop in women with concurrent or prior uterine leiomyomas, and this condition is termed leiomyomatosis. In such cases, malignant metastases from a leiomyosarcoma must be excluded.

Intravenous leiomyomatosis invades and extends serpiginously into the uterine veins, vena cava, and even cardiac chambers (Ma, 2016). With a multidisciplinary team, surgical resection, including hysterectomy and adnexectomy, is preferred treatment (Yang, 2018).

Benign metastasizing leiomyomas derive from morphologically benign uterine leiomyomas that disseminate hematogenously. The slow-growing lesions are found most often in the lungs (Barnaś, 2017). Once diagnosed, excision of symptomatic accessible lesions is reasonable. Multiple masses or pulmonary lesions can be surveilled if asymptomatic or can be treated with castrating surgery or drugs (Pacheco-Rodriguez, 2016).

Disseminated peritoneal leiomyomatosis (DPL) appears as numerous, small peritoneal nodules in the abdominal cavity and often mimics widespread peritoneal metastatic cancer. DPL is usually found in women of reproductive age and is often associated with pregnancy or COC use. Conservative surgery permits diagnosis. Then, treatment typically is cessation of exogenous hormones or antiestrogenic agents to prompt myoma regression (Bisceglia, 2014).

Last, with use of electromechanical morcellation during MIS, multiple small peritoneal leiomyomas may be found later after the primary surgery. Secondary implantation of myoma remnants is implicated, and these present similarly to parasitic leiomyomas or DPL (Tulandi, 2016).

HEMATOMETRA

In this condition, outflow obstruction traps blood and distends the uterus. Depending on the level of the genital tract blockage, blood can variably distend the vagina (hematocolpos), cervix (hematotrachelos), the uterus (hematometra), and fallopian tubes (hematosalpinx). Obstruction may be congenital, and these are described in Chapter 19. Acquired abnormalities such as scarring and neoplasms can also obstruct menstrual flow. As such, hematometra may follow radiation treatment, prolonged hypoestrogenism with atrophy, or surgeries of the endometrial cavity or endocervical canal, particularly cervical conization or endometrial ablation. With postablation tubal sterilization syndrome (PATSS), the occluded fallopian tube and postoperative obstructive synechiae serve as the outflow obstruction (Chap. 44, p. 1061) (McCausland, 2010). Other predisposing conditions are Asherman syndrome or malignancies of the uterus or cervix. Rarely, acute hematometra will follow suction aspiration of the gravid uterus and requires re-aspiration to alleviate (Chap. 43, p. 972) (Sherer, 2011).

Hematometra classically produces suprapubic or low back pain or pelvic fullness. With total obstruction, amenorrhea is noted. If significant, a large uterus can even compress the bladder or rectum to yield urinary retention or constipation. With partial obstruction, blood may erratically drain around the blockage and can be foul. Last, blood may become infected, and pyometra creates fever and leukocytosis.

Pelvic examination findings include an enlarged, soft, or even cystic midline uterine corpus that may be tender to palpation.

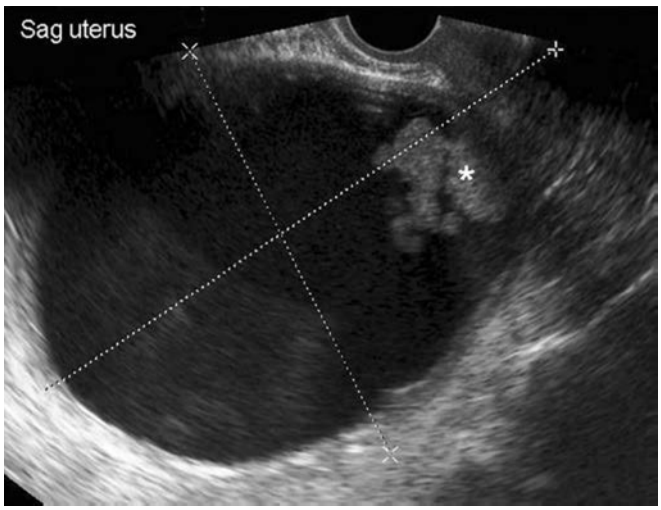

FIGURE 9-8 Sonographic transvaginal sagittal image of hematometra. The uterine walls and proximal cervix are dilated by retained blood, which appears hypoechoic. An obstructive cervical cancer is marked by an asterisk.

Urine or serum β-hCG assay is obtained to exclude pregnancy. Sonography is a principal diagnostic tool, and imaging shows a smooth, symmetric hypoechoic enlargement of the uterine cavity and low-level internal echoes (Fig. 9-8). A hematosalpinx is seen less commonly as a hypoechoic tubular structure lateral to the uterus. Although typically not required for the diagnosis, MR imaging can be used in some cases to help localize the obstruction and to provide additional anatomic information. Importantly, in cases in which the underlying cause is unclear, Pap testing and endocervical and endometrial biopsy are usually indicated to exclude malignancy.

For most cases of hematometra, relief of the obstruction and blood evacuation are goals. Cervical dilatation in the clinic or operating suite usually relieves the accumulation. Some have described hysteroscopy following dilatation to access blood pockets and to lyse adhesions in cases complicated by uterine synechiae (Cooper, 2000). Congenital abnormalities may require more extensive procedures to correct the obstruction.

ADENOMYOSIS

Pathophysiology

Adenomyosis is characterized by uterine enlargement caused by ectopic rests of endometrium—both glands and stroma—located deep within the myometrium (Fig. 9-9). These rests may be scattered throughout the myometrium—*diffuse adenomyosis*, or may form a localized nodular collection—*focal adenomyosis*. Incidences in hysterectomy specimens vary depending on the histologic criteria and on the degree of sectioning but range from 20 to 40 percent (Vercellini, 2006). In one clinic population undergoing TVS, adenomyosis was suspected in 21 percent (Naftalin, 2012).

On gross examination, the uterus is often globally enlarged, but this rarely exceeds 12-week size. The uterine surface is usually smooth, regular, reddish, and soft. The grossly cut myometrium typically appears spongy or trabeculated and shows focal areas of hemorrhage. An example is seen in the next section.

The most widely held theory regarding adenomyosis development describes the downward invagination of the endometrial basalis layer into the myometrium. Mechanisms are unknown, but prior uterine surgery and estrogen and progesterone likely play a role in its development and maintenance. Adenomyosis is also associated with aromatase expression and higher tissue estrogen levels (Yamamoto, 1993). This similar increase is also seen in leiomyomas, endometrial hyperplasia, and endometriosis, which are often coexistent with adenomyosis. However, endometriosis differs from adenomyosis in its pathogenesis and epidemiology. Adenomyosis derives from the basalis layer, but endometriosis stems from the functionalis.

Parity and age are significant risk factors for adenomyosis (Templeman, 2008). Specifically, nearly 90 percent of cases are in

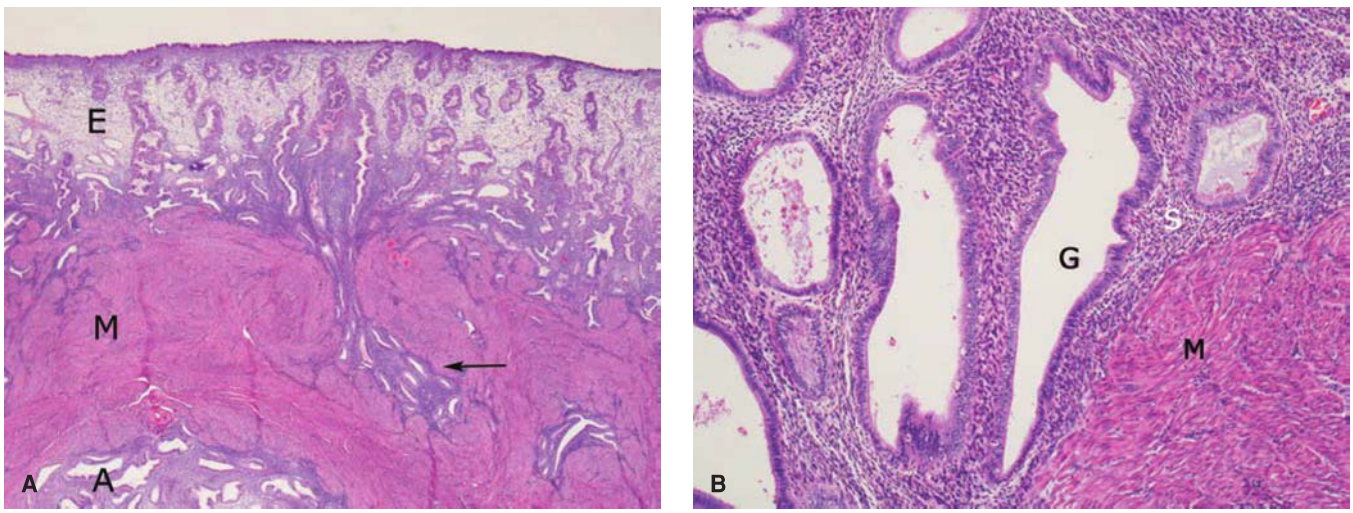

FIGURE 9-9 **A.** In adenomyosis, endometrial glands and their surrounding stroma dip irregularly into the myometrium (*arrow*). A = adenomyosis; E = endometrium; M = myometrium. **B.** Higher magnification view. Endometrial glands (*G*) and stroma (*S*) are seen adjacent to myometrium (*M*). (Reproduced with permission from Dr. Kelley Carrick.)

parous women, and nearly 80 percent develop in women in their 40s and 50s (Bird, 1972; Lee, 1984). It regresses after menopause.

Diagnosis

Approximately one third of women with adenomyosis have symptoms, and HMB and dysmenorrhea are common. Perhaps 10 percent complain of dyspareunia. Symptom severity correlates with increasing number of ectopic foci and extent of invasion (Levgur, 2000). Any link with subfertility is unclear, as data are scarce and poor quality (Maheshwari, 2012).

For diagnosis, transabdominal sonography inconsistently identifies the often subtle myometrial changes of adenomyosis, and imaging with TVS is preferred (Bazot, 2001). In comparison, MR imaging may be equal or slightly superior to TVS (Reinhold, 1996). Thus, MR imaging may be most appropriate when the diagnosis is inconclusive, when further delineation would affect patient management, or when coexisting uterine myomas distort anatomy (American College of Obstetricians and Gynecologists, 2016). With TVS, findings of diffuse adenomyosis may include: (1) anterior or posterior myometrial wall appearing thicker than its counterpart, (2) myometrial texture heterogeneity, (3) small myometrial hypoechoic cysts, which are cystic glands within ectopic endometrial foci, (4) striated projections extending from the endometrium into the myometrium, (5) ill-defined endometrial echo border, and (6) a globally enlarged uterus (Fig. 9-10). With application of color or power Doppler, diffuse vascularity may be seen in affected myometrium. Focal adenomyosis appears as a discrete hypoechoic nodule that may sometimes be differentiated from leiomyomas by its poorly defined margins, elliptical shape, minimal mass effect on surrounding tissues, and lack of calcifications, but presence of small anechoic myometrial cysts (Levy, 2013).

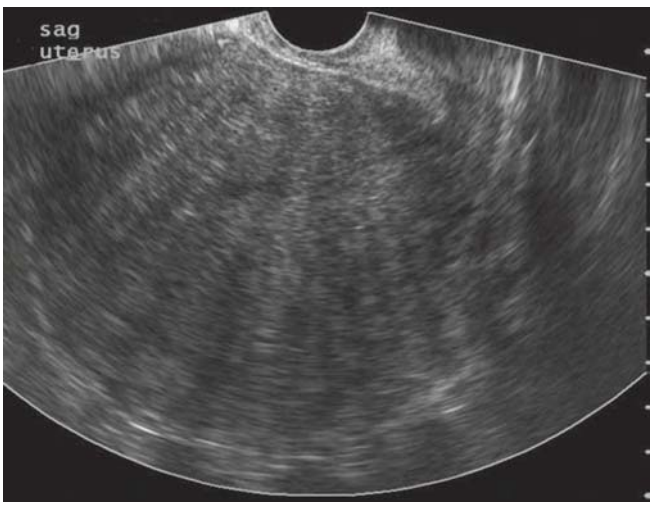

FIGURE 9-10 Transvaginal sagittal uterine image displaying globular uterine enlargement and heterogeneous myometrial texture. Uterine wall thickening can show anteroposterior asymmetry, and here the posterior wall is thicker. In this image, the endomyometrial junction is also poorly defined. Last, a "shutter blind" effect is thought to reflect endometrial gland invasion into the subendometrial tissue and appears as echogenic linear striations.

Management

Treatment goals are relief of pain and bleeding. Although supportive data specific to adenomyosis are limited, conservative therapy for symptomatic adenomyosis is similar to that for endometriosis. First, cyclic NSAIDs are often given with menses. In small studies, COCs and progestin-only regimens can be used to induce endometrial atrophy and lower endometrial prostaglandin production to improve dysmenorrhea and HMB (Muneyyirci-Delale, 2012; Osuga, 2017). Also, the LNG-IUS has proved effective for treatment of adenomyosis-related bleeding (Shaaban, 2015). Notably, expulsion rates may be higher in affected women (Youm, 2014). GnRH agonists are another effective choice, although their high cost and hypoestrogenic side effects typically limit long-term use. These agonists may be most helpful for women with adenomyosis-related subfertility or as relief prior to surgical treatment. Although danazol may be considered, it is often a less desirable option due to its androgenic side effects.

Hysterectomy is definitive treatment. As with other conditions, surgical route selection is influenced by uterine size and associated uterine or abdominopelvic pathology. Alternatively, global endometrial ablation or hysteroscopic endometrial resection has successfully treated dysmenorrhea and HMB caused by adenomyosis (Preutthipan, 2010). However, failure rates may be higher in women with adenomyosis (Wishall, 2014). By 3 years in one small study, 19 percent of ablation-treated women with adenomyosis ultimately underwent hysterectomy (Philip, 2018). Complete eradication of deep adenomyosis is problematic and is thought responsible for a significant number of treatment failures (Mengerink, 2015). Accordingly, some recommended imaging prior to ablation to identify these deep lesions and allow better patient selection (McCausland, 1996).

UAE can also relieve symptoms for some women with adenomyosis, although study sizes are small (Chen, 2006; Liang, 2018). One systematic review found that 90 percent of women with adenomyosis were improved short-term (de Bruijn, 2017). After 1 year, 74 percent still benefited. In another, investigators following women 1 to 5 years after UAE found 65 percent were still improved (Popovic, 2011). For focal adenomyomas, MRgFUS was effective in small case series (Yang, 2009; Zhang, 2014).

OTHER UTERINE ENTITIES

Myometrial hypertrophy is global uterine enlargement without identifiable pathology, especially in those with high parity (Traiman, 1996). Also known as gravid hypertrophy, one definition includes uterine weights >130 g for nulliparas and >210 g for multiparas (Zaloudek, 2011). Symptoms are infrequent, but HMB is a common complaint.

Uterine or cervical diverticula are sacculations that communicate with and extend out from the endometrial cavity or endocervical canal. Rarely, these are congenital anomalies developing from a localized duplication of the distal müllerian duct on one side (Engel, 1984). More often, defects are acquired, develop in the uterine isthmus, and follow cesarean delivery (Fig. 9-11). These *isthmoceles* may cause postmenstrual spotting or intermenstrual bleeding. Also termed *cesarean scar*

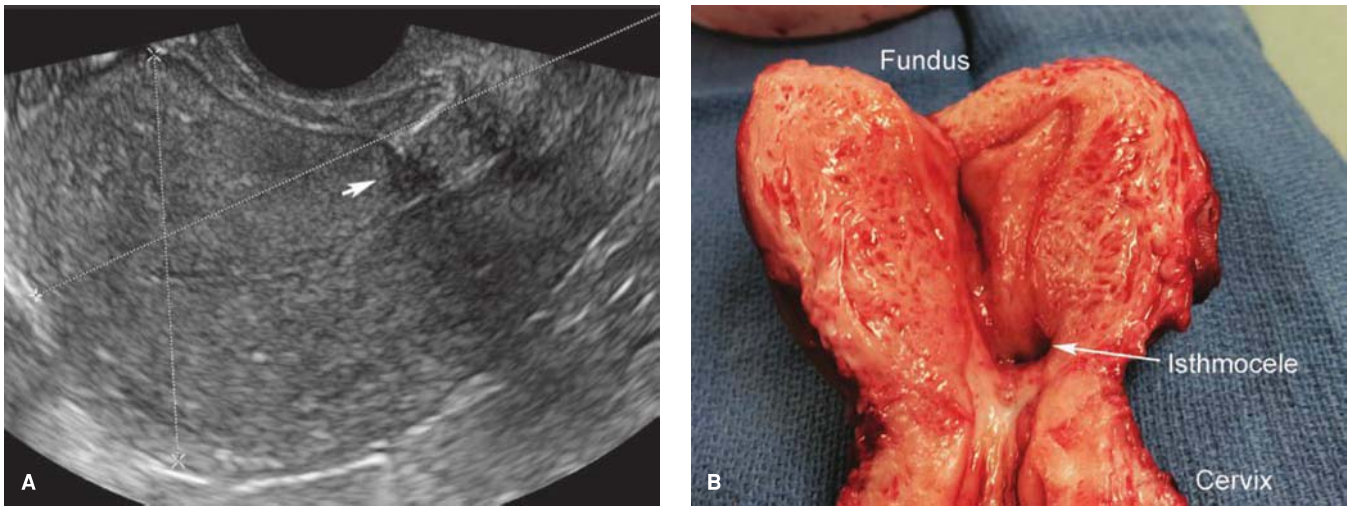

FIGURE 9-11 Isthmocele. **A.** In this sagittal sonogram, the cesarean scar niche is the hypoechoic triangle marked by the arrow. **B.** The same uterus is seen after hysterectomy. In this specimen, comorbid adenomyosis is identified by the highly trabeculated myometrium. (Reproduced with permission from Dr. David Rogers.)

defects, these niches can serve as a passive repository for menstrual blood and release it during postmenstrual days. Also, cesarean scar pregnancies may result from blastocyst implantation within the isthmocele (Chap. 7, p. 171).

Although niches can be seen during TVS, defects are best imaged by SIS and can be identified hysteroscopically (Antila-Långsjö, 2018; Bij de Vaate, 2011). MR imaging is also informative but less cost effective than SIS.

Endometrial suppression with COCs has been described (Tahara, 2006). Although data are lacking, progestins alone might also be helpful. The LNG-IUS appears less effective (Zhang, 2016a). Surgical options include hysterectomy or hysteroscopic shaving of niche edges plus ablation of the pouch base (Vervoort, 2018; Setubal, 2018). Another option is excision of the involved myometrium followed by reapproximation of muscle edges. This last method has been described laparoscopically and transvaginally (Zhang, 2016b). Data are limited regarding the superiority of one surgical approach compared with another for symptom relief or for future childbearing. However, in those with thinner myometrium (<3 mm) at the site, hysteroscopic resection may pose greater perforation risk (Sanders, 2018).

OVARIAN CYSTS AS A GROUP

Ovarian masses are a frequent finding in general gynecology, and most are cystic (Fig. 10-1). Histologically, ovarian cysts are often divided into those derived from neoplastic growth, *ovarian cystic neoplasms*, and those created by disruption of normal ovulation, *functional ovarian cysts*. Differentiation of these is not always clinically apparent using either imaging or tumor markers. Thus, ovarian cysts are often managed as a single composite clinical entity, and the next sections describe this general approach. Later sections discuss discrete pathologies.

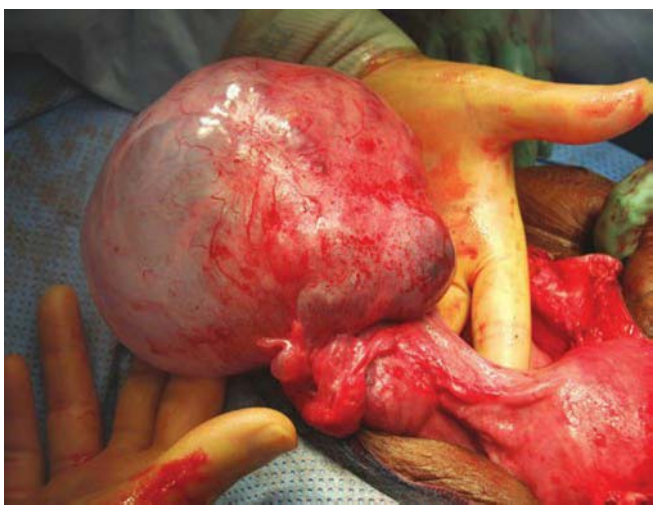

FIGURE 10-1 Intraoperative photograph of a large benign mucinous cystadenoma. The fimbriated end of the fallopian tube is seen below the ovary, and the uterus lies at the lower right. (Reproduced with permission from Dr. Eddie McCord.)

The exact mechanisms leading to cyst formation are unclear. Angiogenesis is an essential component of both the follicular and luteal phases of the ovarian cycle. It is also a component of various pathologic ovarian processes. Some include follicular cyst formation, polycystic ovarian syndrome (PCOS), ovarian hyperstimulation syndrome, and benign and malignant ovarian neoplasms.

The incidence of ovarian cysts varies only slightly with patient demographics and ranges from 5 to 15 percent (Dorum, 2005; Millar, 1993). Functional ovarian cysts make up a large portion. Neoplasms constitute most of the remainder, and these predominantly are benign. In their review of U.S. inpatient hospitalizations for 2010, Whiteman and colleagues (2010) reported that approximately 7 percent of gynecologic admissions were for benign ovarian cysts.

Management goals include identifying malignancy and treating symptoms while preserving ovarian function when possible and minimizing overtreatment. However, despite continuous improvement in diagnostic methods, it is often impossible to clinically differentiate between benign and malignant conditions. Thus, management must balance the surgical morbidity from excision of an innocent lesion with the risk of not removing an ovarian malignancy.

Symptoms

Most women with ovarian cysts are asymptomatic. If symptoms develop, pain is common. Dysmenorrhea may indicate endometriosis and an associated endometrioma. Intermittent or acute severe pain with vomiting often accompanies torsion. Other causes of acute pain include cyst rupture or tuboovarian abscess. In contrast, pressure or ache may be the sole symptom and can result from ovarian capsule stretching or cyst bulk. In ovarian malignancies, diagnosis depends on providers having a high index of suspicion in symptomatic women (Schorge, 2010). In some affected individuals, evidence of hormonal disruption is found. For example, excess estrogen production from granulosa cell stimulation may disrupt normal menstruation or initiate bleeding even in prepubertal or postmenopausal patients. Increased androgen levels produced by theca cell stimulation can virilize women.

Diagnosis

Tumor Markers

Many ovarian cysts are asymptomatic and found incidentally on routine pelvic examination or during imaging studies for another indication. Findings vary, but typically masses are mobile, cystic, nontender, and found lateral to the uterus.

Serum β-human chorionic gonadotropin (hCG) testing is invaluable for adnexal pathology evaluation. Detection of serum β-hCG may indicate ectopic pregnancy or a corpus luteum of pregnancy. Less commonly, β-hCG also can serve as a tumor marker in defining germ cell neoplasms.

Other tumor markers are typically proteins produced by cancer cells or by the body in response to tumor cells. Of markers used, cancer antigen 125 (CA125) is an antigenic determinant on a high-molecular-weight glycoprotein produced by mesothelial cells that line the peritoneal, pleural, and pericardial cavities. Serum CA125 levels are often elevated in women with epithelial ovarian cancer. Unfortunately, CA125 is not a tumor-specific antigen, and concentrations are elevated in up to 1 percent of healthy controls. Levels may also rise in women with nonmalignant disease such as leiomyomas, endometriosis, adenomyosis, and salpingitis. Despite these limitations, serum CA125 determinations may be helpful and are often obtained if ovarian cysts are large or have sonographically worrisome signs described in the next section. Cysts in patients who are postmenopausal or who carry a *BRCA* gene mutation also may warrant CA125 level evaluation (Chap. 35, p. 740).

Of other markers, elevated carcinoembryonic antigen (CEA) and cancer antigen 19-9 (CA19-9) levels arise from secretions of mucinous epithelial ovarian carcinomas. Serum alpha-fetoprotein (AFP) levels may be elevated in those patients with a rare endodermal sinus tumor or embryonal cell carcinoma. Increased serum levels of β-hCG may indicate an ovarian choriocarcinoma, a mixed germ cell tumor, or embryonal cell carcinoma. Inhibin A and B are markers for granulosa cell tumors. Last, lactate dehydrogenase (LDH) levels may be higher in those with dysgerminoma.

OVA1 is a biomarker blood test panel and considered a *multivariate index assay* that can be used in women with an identified ovarian mass warranting surgery (Ueland, 2011; Ware Miller, 2011). Scores ≥5.0 in premenopausal and scores ≥4.4 in postmenopausal women suggest a need for gynecologic oncologist consultation (Table 10-1).

Another marker, human epididymal protein 4 (HE4), is coupled with CA125 in the Risk of Ovarian Malignancy Algorithm (ROMA). This algorithm helps predict the likelihood of finding malignancy at surgery in women with known adnexal masses to aid presurgical triage. The ROMA score is derived from the results of both blood tests plus menopausal status (Moore, 2009, 2010).

Similarly, the risk of malignancy index (RMI) algorithm factors menopausal status, CA125 serum level, and sonographic score. This last element is derived from ovarian appearance, and presence of ascites or intraabdominal metastases (Jacobs, 1990; Karlsen, 2012).

None of these three tests is a screening tool, nor are their findings absolute. They are reserved for those with a known surgical mass to guide specialty referral.

Imaging

Sonography is a first-line tool to evaluate pelvic masses. Transabdominal scanning is performed first to avoid missing a large cyst that lies outside the pelvis. For lesions confined within the true pelvis, transvaginal sonography (TVS) has superior resolution. Characteristic findings for specific types of ovarian cysts have been defined to help discriminate malignant from benign lesions (Table 10-2). Specifically, thick septa with increased vascularity, papillary intracystic growths, and solid elements within the cyst raise concern.

Traditional grayscale sonography can be augmented with color Doppler. Described in Chapter 2 (p. 30), transvaginal color Doppler sonography depicts blood flow to and within a pelvic mass. This can add information regarding lesion structure, malignant potential, and possible torsion. However, for assessing simple ovarian cysts and the risk of malignancy, the application of color Doppler typically provides no significant advantage compared with conventional TVS (Vuento, 1995).

Sonographic color Doppler and spectral analysis of flow signals are combined with tumor size and morphology in several scoring systems to help differentiate malignant and benign masses (Chap. 2, p. 30). As an example, using these sonographic features, the International Ovarian Tumor Analysis (IOTA) Group developed accurate mathematic models to calculate malignancy risk (Timmerman, 2000, 2005, 2016). Several other sonographic scoring systems have been evaluated. At our institution, we use the Ovarian Tumor Index developed by Twickler and colleagues (1999).

TABLE 10-1. Indications for Referral of a Suspicious Ovarian Mass to a Gynecologic Oncologist

Clinical Indicator	Premenopausal Woman	Postmenopausal Woman
CA125	Very elevated	Elevated (>35 U/mL)
Sonography	Suggests malignancy	Suggests malignancy
Other imaging	Ascites	Ascites
	Abdominal or distant metastasis	Abdominal or distant metastasis
Physical finding	—	Nodular or fixed pelvic mass
Presurgical triage tool		
ROMA	Laboratory-dependent thresholds	
MIA (OVA1)	≥5.0	≥4.4
RMI	>200	>200

CA125 = cancer antigen 125; MIA = multivariate index assay; RMI = Risk of Malignancy Index; ROMA = Risk of Malignancy Algorithm.

TABLE 10-2. Recommended Management of Asymptomatic Ovarian Masses Found with Imaging

Type of Ovarian Mass	Recommendation
CYSTS WITH BENIGN QUALITIES	
Simple Cyst	Simple cysts, regardless of patient age, are typically benign
Premenopausal	
≤3 cm diameter	Normal anatomic finding
≤5 cm diameter	No additional treatment required
>5 but ≤7 cm diameter[a]	TVS repeated in 6–12 wks to document resolution; if persistent, then yearly TVS[b]
>7 cm diameter[a]	MRI or surgical evaluation
Postmenopausal	
≤1 cm diameter	Normal anatomic finding
≤5 cm diameter[a]	CA125 level; if normal level, then TVS repeated in 6–12 weeks; if persistent cyst, then yearly TVS[b]
>7 cm diameter[a]	MRI or surgical evaluation
Hemorrhagic Cyst[c]	
Premenopausal	
≤3 cm diameter CL	Normal anatomic finding
≤5 cm diameter	No additional treatment required
>5 but ≤7 cm diameter	TVS repeated in 6–12 weeks; if persistent, then consider MRI or surgical evaluation
Early postmenopausal[d]	CA125 level; if normal, then TVS repeated in 6–12 weeks; if persistent cyst, then
Any size	consider MRI or surgical evaluation
Late postmenopausal[d]	Surgical evaluation
Any size	
Endometrioma	TVS repeated in 6–12 weeks; if persistent, then yearly TVS[b]
Mature cystic teratoma	If not surgically removed[e], then yearly TVS[b]
Hydrosalpinx	May be observed as clinically indicated
Peritoneal inclusion cyst	May be observed as clinically indicated
CYSTS WITH INDETERMINATE, BUT PROBABLY BENIGN QUALITIES	
Indeterminate for: hemorrhagic cyst, mature cystic teratoma, endometrioma	
Premenopausal	TVS repeated in 6–12 weeks; if persistent cyst, then consider surgical evaluation or MRI
Postmenopausal	Consider surgical evaluation
Thin-walled cyst with single thin septation or focal cyst wall calcification	Same as for simple cyst
Multiple thin septations (<3 mm)	Consider surgical evaluation
Nodule (non-hyperechoic) without flow	Consider surgical evaluation or MRI
CYSTS WITH QUALITIES SUGGESTING MALIGNANCY	
Thick (>3 mm) irregular septations	Consider surgical evaluation
Nodule with blood flow	Consider surgical evaluation

[a]The American College of Obstetricians and Gynecologists (2016) recommends a threshold up to 10 cm for simple cysts in all age groups.
[b]Shorter time interval may be selected for surveillance as clinically indicated.
[c]Color Doppler as an adjunct is recommended to exclude solid components.
[d]All postmenopausal women with an adnexal mass also undergo breast and digital rectal examination and mammography, if not already performed in the last year due to the high rate of metastasis from other primary tumors to the ovary.
[e]Some studies have found that stable small mature cystic teratomas with a confident diagnosis may be observed in premenopausal women.
CA125 = cancer antigen 125; CL = corpus luteum; MRI = magnetic resonance imaging; TVS = transvaginal sonography.
From American College of Obstetricians and Gynecologists, 2016; Atri, 2019; Levine, 2010.

Computed tomography (CT) or magnetic resonance (MR) imaging of an ovarian cyst may clarify situations in which anatomy or patient habitus complicates sonographic imaging. CT is best used when malignancy is suspected to evaluate for metastasis, ascites, or lymphadenopathy (American College of Obstetricians and Gynecologists, 2016). However, in most clinical settings, sonography alone is suitable (Atri, 2019; Outwater, 1996).

Management

Observation

In prepubertal and reproductive-aged women, most ovarian cysts are functional and spontaneously regress within 6 months of identification. For postmenopausal women with a simple ovarian cyst, expectant management also may be reasonable if several criteria are met. These are: (1) sonographic evidence of a thin-walled, unilocular cyst; (2) cyst diameter <5 cm; (3) no cyst enlargement during surveillance; and (4) normal serum CA125 level (Nardo, 2003). Moreover, the American College of Obstetricians and Gynecologists (2016) notes that simple cysts up to 10 cm in diameter by sonographic evaluation may safely be followed even in postmenopausal women. Consensus regarding an end point for observation is lacking. Some experts recommend 1 year of surveillance for patients with stable adnexal masses without solid components and 2 years for those with stable masses with solid components (Suh-Bergmann, 2014, 2015). With any surveillance plan, the risks of potentially serious pathology and patient anxiety are weighed against surgical morbidity.

Surgery

Both malignant and benign cysts show considerable morphologic similarity. For diagnosis, ovarian cyst aspiration usually is avoided because of possible intraperitoneal seeding by early-stage ovarian cancer. Moreover, false-positive and false-negative results are common (Martinez-Onsurbe, 2001; Moran, 1993). Accordingly, for many cases, cyst excision serves as the definitive diagnostic tool.

With suspected ovarian cancers, optimal surgical resection and proper staging by a gynecologic oncologist during the primary operation are major factors in long-term patient survival. Thus, women with pelvic masses and preoperative findings suspicious for malignancy are generally referred. The American College of Obstetricians and Gynecologists (2017) and Society of Gynecologic Oncologists have jointly presented guidelines regarding clinical criteria that should prompt preoperative referral to a gynecologic oncologist (see Table 10-2).

For the generalist, cysts presumed to be benign may be excised or the whole ovary may be removed. Of these, cystectomy offers the advantage of ovarian preservation but risks cyst rupture and content spill. With ovarian cancer, such spill and subsequent malignant seeding can worsen patient prognosis. Thus, the decision for one surgical technique in preference over the other is influenced by lesion size, patient age, and intraoperative findings. For example, in premenopausal women, smaller lesions generally require only cystectomy with preservation of reproductive function. Larger lesions may prompt oophorectomy because of their greater risk for rupture during enucleation, difficulty in reconstructing ovarian anatomy following large cyst removal, and the increased risk of malignancy in these bigger cysts. However, in postmenopausal women, oophorectomy is preferred because the risk for cancer is higher. The ovaries in these women are also no longer providing sufficient estrogen production or fertility potential (Okugawa, 2001).

The surgical route is also dictated by clinical factors. Laparoscopy and minilaparotomy are the more common approaches to a benign adnexal mass. Advantages of these minimally invasive techniques compared with laparotomy include reduced pain, length of stay, incidences of postoperative fever, and complication rates (Medeiros, 2009). However, during laparoscopic cystectomy or oophorectomy, cyst size must allow suitable optics. Moreover, laparoscopic instruments must have sufficient room to interact effectively and to create tissue tension. Contained cyst removal without morcellating the ovarian cortex also is desirable in cases with an intermediate risk of malignancy.

If these requisites cannot be achieved, minilaparotomy may be preferred. With smaller cysts, excision and removal can be completed through the incision. For larger cysts, primary decompression through the incision can then permit excision and extraction of the entire specimen.

Last, women with large cysts or other factors indicating a higher malignancy risk often are managed by laparotomy. With a greater potential for malignancy, a midline vertical incision provides a surgical field large enough for oophorectomy or cyst enucleation without tumor rupture and for surgical staging if malignancy is found.

Clinical findings of an unexpected malignancy at the time of surgery will dictate further actions. Multiple small lesions studding the peritoneal surface, ascites, and exophytic growths extending from the ovarian capsule should prompt collection of peritoneal fluid for cytologic study and intraoperative frozen section analysis. If cancer is found, a gynecologic oncologist is ideally consulted intraoperatively. At minimum, limited clinical staging, as discussed in Chapter 35 (p. 747), can be completed.

FUNCTIONAL OVARIAN CYSTS

These are common, originate from ovarian follicles, and are created during follicle maturation and ovulation. They are subcategorized as either *follicular cysts* or *corpus luteum cysts* based on both their pathogenesis and histologic qualities. They are not neoplasms and derive mass from accumulation of intrafollicular fluids rather than cellular proliferation. With follicular cyst formation, hormonal dysfunction prior to ovulation results in expansion of the follicular antrum with serous fluid. In contrast, excessive hemorrhage from the vascular corpus luteum following ovulation may fill its center to create a corpus luteum cyst. Thus, follicular and corpus luteum cysts differ in their genesis, but symptoms and management are similar.

Associated Factors

Of potential factors, high-dose combination oral contraceptives (COCs) suppress ovarian activity and protect against cyst development (Ory, 1974). However, in subsequent studies

with low-dose pills, which contain 35 μg of ethinyl estradiol or less, COCs provided only modest protective effects (Holt, 2003; Lanes, 1992). By contrast, the incidence of follicular cysts is increased with many progestin-only contraceptives. Recall that continuous, low-dose progestins do not completely suppress ovarian function. As a result, dominant follicles may develop in response to gonadotropin secretion. Yet, the normal ovulatory process is frequently disrupted, and follicular cysts develop. Clinically, follicular cysts are found with greater frequency in those using the levonorgestrel-releasing intrauterine system (LNG-IUS) and progestin-releasing implants (Hidalgo, 2006; Nahum, 2015).

Both pre- and postmenopausal women treated with tamoxifen for breast cancer have a higher risk for benign ovarian cyst formation (Chalas, 2005; Simpkins 2005). Premenopausal women and women with greater body mass index are disparately affected. Most are functional cysts that resolve with time whether tamoxifen treatment is continued or discontinued (Cohen, 2003). If small simple cysts are found, sonographic surveillance is reasonable. If clinical signs of malignancy are present, surgical exploration is indicated, and tamoxifen is discontinued. Of other selective estrogen-receptor modulators, bazedoxifene, raloxifene, and ospemifene do not appear to raise ovarian cyst rates (Archer, 2015).

Several epidemiologic studies have linked smoking with functional cyst development (Holt, 2005; Wyshak, 1988). Although the exact mechanism(s) is unknown, changes in gonadotropin secretion and ovarian function are suspected (Michnovicz, 1986).

Diagnosis and Treatment

Functional cysts are managed similarly to other cystic ovarian lesions. Consequently, sonography is initially performed. Typical follicular cysts are completely rounded anechoic lesions with thin, regular walls (Fig. 10-2). Conversely, corpus luteum cysts are termed "great imitators" because of their varied and evolving sonographic characteristics (Fig. 10-3). With a corpus luteum, transvaginal sonography and applied color Doppler typically display a brightly colored ring because of enhanced vascularity surrounding the cyst. This *ring of fire* also is common to ectopic pregnancies (Fig. 7-5, p. 166).

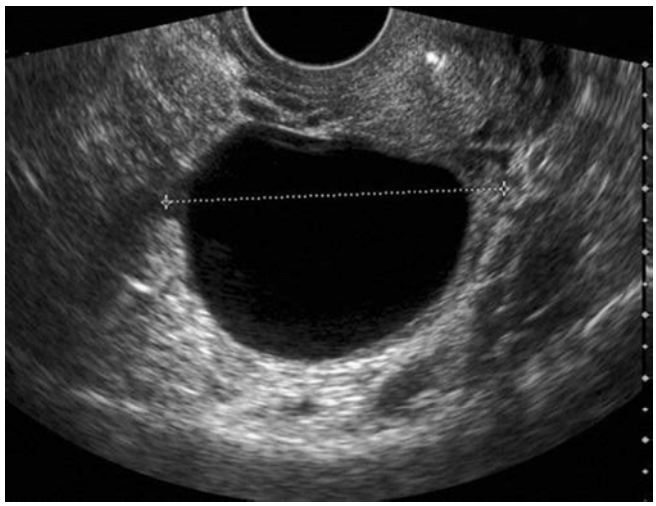

FIGURE 10-2 Sonographic transvaginal image of an ovary containing a follicular cyst. Note the smooth walls and lack of internal echoes. (Reproduced with permission from Dr. Elysia Moschos.)

If asymptomatic, women with findings of a functional ovarian cyst usually are observed. Spontaneous regression of these cysts is anticipated, and COC use does not hasten resolution (Grimes, 2014). Patients undergoing surveillance are advised of the symptoms of ovarian torsion. Surgical excision may be reasonable for large persistent cysts, usually those >10 cm, or for smaller ones producing persistently bothersome symptoms. Enlarging cysts are typically removed.

Theca Lutein Cysts

These are an uncommon type of follicular cyst, characterized by luteinization and hypertrophy of their theca interna layer. Bilateral, multiple smooth-walled cysts form and range in size from 1 to 4 cm in diameter. Termed *hyperreactio lutealis*, this condition is thought to be prompted by elevated luteinizing hormone or β-hCG levels. Commonly associated conditions include gestational trophoblastic disease, multifetal gestation, placentomegaly, and ovarian hyperstimulation during assisted reproductive techniques (Fig. 37-4, p. 776). These cysts typically resolve spontaneously following removal of the stimulating hormone source. However, prior to this, these bulky ovaries are at risk for torsion.

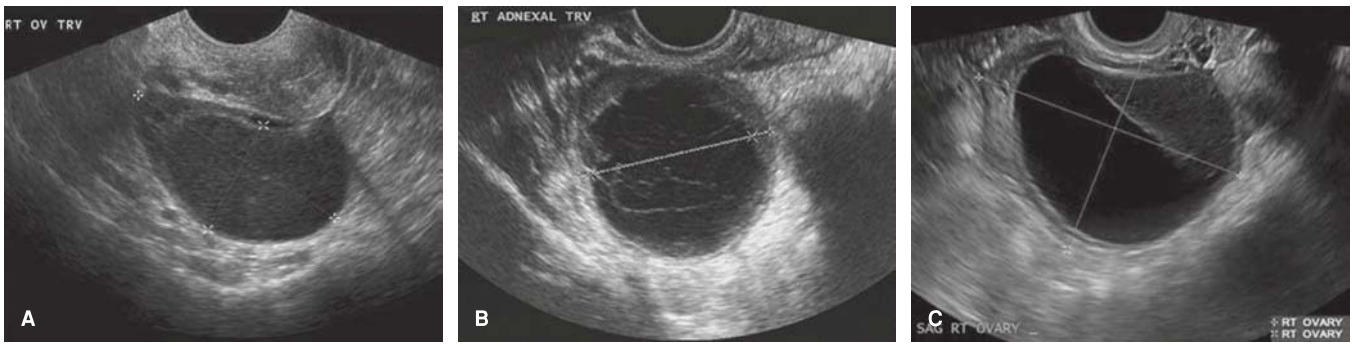

FIGURE 10-3 Sonographic transvaginal transverse images of hemorrhagic corpus luteum cysts. **A.** Diffuse low-level echoes, which are commonly associated with recent hemorrhage, are seen throughout this smooth-walled cyst. **B.** With evolution of the clot, a lacy reticular pattern develops. **C.** As the clot hemolyzes, a distinct line often forms between the serum and retracting clot. With further retraction, the clot may appear as an intramural nodule. (Reproduced with permission from Dr. Elysia Moschos.)

BENIGN NEOPLASTIC OVARIAN CYSTS

These lesions, in combination with functional ovarian cysts, constitute most ovarian masses. Ovarian neoplasms can be distinguished histologically depending on their cell type of origin. These are grouped as epithelial tumors, germ cell tumors, sex cord–stromal tumors, and others shown in Table 10-3. Of benign ovarian neoplasms, serous and mucinous cystadenomas and mature cystic teratoma are the most common (Pantoja, 1975).

Benign Serous and Mucinous Tumors

These are members of the surface epithelial neoplasia group, and both are lined by cells similar to those lining the fallopian tube. *Benign serous tumors* are typically thin-walled, unilocular cysts filled with serous fluid (Fig. 10-4). They are bilateral in up to 20 percent of cases. *Benign mucinous tumors* are typically thicker-walled, mucoid-containing tumors that may be small but can often attain large diameters. They may be uni- or multilocular.

In categorizing tumors within the epithelial family, benign tumors are designated as *adenomas*; malignant tumors, as *carcinomas*; and those with exuberant cellular proliferation without invasive behavior as *low malignant potential* (Chen, 2003). The prefix *cyst-* describes predominantly cystic neoplasms. In addition, in most of these tumors, the epithelial component dominates. In those in which ovarian stroma predominates, the suffix *–fibroma* is used. Thus, *serous cystadenofibroma* describes a benign, mainly cystic tumor of the ovarian epithelial tumor group in which stromal components predominate (Prat, 2009).

Ovarian Teratoma

These belong to the germ cell family of ovarian neoplasms. Teratomas arise from a single germ cell, and therefore may contain any of the three germ layers—ectoderm, mesoderm, or endoderm. These layers are typically disorganized.

Teratomas are classified as:

Immature teratoma—This neoplasm is malignant and described in Chapter 36 (p. 760). Immature tissues from one, two, or all three germ cell layers are found and often coexist with mature elements.

Mature teratoma—This benign tumor contains mature forms of the three germ cell layers:

1. Mature cystic teratoma develops into a cyst, is common, and may also be called *benign cystic teratoma* or *dermoid cyst*.
2. Mature solid teratoma has elements formed into a solid mass.
3. Fetiform teratoma or homunculus forms a doll-shape, as the germ cell layers display considerable normal spatial differentiation.

Monodermal teratoma—This benign tumor is composed either solely or predominantly of only one highly specialized tissue type. Of the monodermal teratomas, those composed dominantly of thyroid tissue are termed *struma ovarii*.

Of these teratoma types, mature cystic teratoma is by far the most common. These benign tumors constitute approximately 10 to 25 percent of all ovarian neoplasms and 60 percent of all benign ovarian neoplasms (Koonings, 1989; Peterson, 1955). These cystic tumors are typically slow growing, and most measure between 5 and 10 cm (Comerci, 1994). They are bilateral in approximately 10 percent of cases (Peterson, 1955). When sectioned, most cysts appear unilocular and typically contain one area of localized growth, which protrudes into the cystic cavity. Alternatively designated as *Rokitansky protuberance*, *dermoid plug*, *dermoid process*, *dermoid mamilla*, *or embryonal rudiment*, this protuberance can be absent or multiple.

Microscopically, endodermal or mesodermal derivatives may be found, but ectodermal elements usually predominate. The cyst is typically lined with keratinized squamous epithelium and contains abundant sebaceous and sweat glands. Hair and fatty secretions are often found within (Fig. 10-5). At times, bone and teeth are identified.

The Rokitansky protuberance is usually the site where the most varied tissue types are found and is a common location

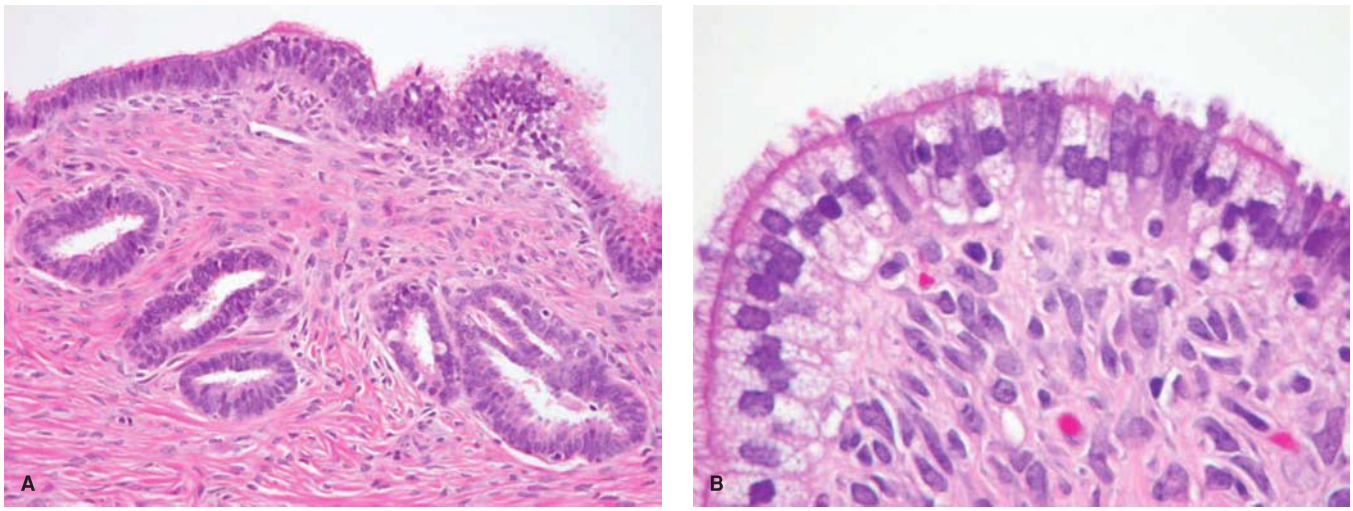

FIGURE 10-4 Serous **(A,B)** and mucinous **(C,D)** cystadenoma. **A.** This simple cyst has a fibrous wall and is lined by a single layer of benign, columnar tubal-type epithelium with cilia. **B.** High-power view of its ciliated, tubal-type lining. **C.** Mucinous cystadenomas are typically multiloculated cysts lined by a single layer of benign mucin-containing epithelium. Mucinous fluid is secreted by the epithelium and contained within the cystic mass. In this image, it is the amorphous material above the epithelium and is stained pink (*asterisk*). **D.** High-power view of simple columnar, mucin-containing epithelium. FIGURE 10-5 **A.** A sectioned mature cystic teratoma following cystectomy. Abundant hair, sebum, and teeth, which are all characteristic of these neoplasms, are evident. **B.** In this classic histologic example, ectodermal elements include skin (*Sk*), sebaceous (*Se*), and eccrine (*E*) glands, whereas mesodermal elements are smooth muscle (*Sm*) and adipose (*A*). (Reproduced with permission from Dr. Kelley Carrick.)

of malignant transformation. This transformation occurs in <2 percent of mature cystic teratomas (Black, 2015; Comerci, 1994). Patients older than 50 years or with masses >10 cm are at greater risk (Chiang, 2017; Park, 2008). Most malignant cases are squamous cell carcinoma.

The diverse tissues found within teratomas do not arise by fertilization of an ovum by sperm. Instead, they are thought to develop from genetic material contained within a single oocyte by asexual *parthenogenesis*. As a result, almost all mature cystic teratomas have a 46,XX karyotype (Linder, 1975).

Mature cystic teratomas often can undergo torsion, but cyst rupture is rare. Presumably, their thick cyst wall resists rupture compared with other ovarian neoplasms. If cysts do spill, acute peritonitis is common, and Fielder and associates (1996) attributed peritonitis to the sebum and hair contents. They showed the benefits of intraoperative lavage to prevent peritonitis and adhesion formation. Chronic leakage of teratoma contents is rare but can lead to granulomatous peritonitis.

Symptoms from these teratomas are similar to those of other ovarian cysts. However, ovarian teratomas can rarely cause immune-mediated encephalitis. Neurologic symptoms stem from antibodies to *N*-methyl-D-aspartate receptors (NMDARs), which have critical roles in synaptic transmission. The diagnosis is confirmed by detecting antibodies in the serum or cerebrospinal fluid. Teratomas are one of several potential causes of this anti-NMDAR encephalitis. The teratomas contain primitive neural tissue, which presumably provides the antigen that prompts NMDAR antibody formation. Teratoma resection is essential to encephalitis resolution, which can often be dramatic. Resection may be combined with immunotherapy (Yan, 2019). In one large series of 100 patients, 75 percent recovered, but 25 percent died or survived with severe deficits (Dalmau, 2008).

Sonography is the main imaging tool, and mature cystic teratomas display several characteristic features (Fig. 10-6). First, fat-fluid or hair-fluid levels are seen as a distinct linear demarcation. Here, intracystic serous fluid interfaces with sebum, which is liquid at body temperature. When floating, hair forms accentuated lines and dots that represent hair in longitudinal and transverse planes. The Rokitansky protuberance is a rounded mural nodule measuring 1 to 4 cm, is predominantly hyperechoic, and creates an acute angle with the cyst wall. Last, the "tip of the iceberg" sign is created by amorphous echogenic interfaces of fat, hair, and tissues in the foreground that shadow and thus obscure structures behind it (Guttman, 1977). Notably, these findings are not exclusive to mature cystic teratomas. For example, Patel and associates (1998) reported modest positive predictive values for these findings individually. However, they described values of 100 percent when two or more were found within a given lesion.

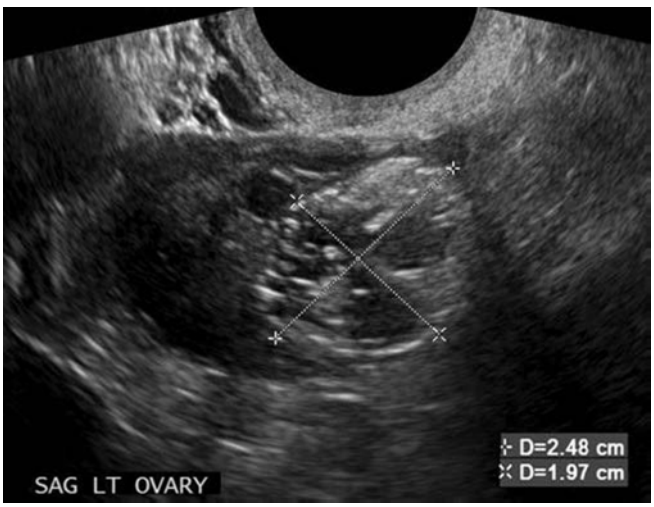

FIGURE 10-6 Sonogram revealing characteristics of mature cystic teratoma, which is measured by calipers. (Reproduced with permission from Dr. Elysia Moschos.)

Of serum markers, increased CA19-9 and CA125 levels may be noted. Of the two, CA19-9 level elevations are seen more often and in approximately 30 percent of cases (Fan, 2016; Kim, 2011; Sagi-Dain, 2015). Thus, this marker occasionally may help differentiate cystic adnexal masses. That said, serum markers are not diagnostic and often unnecessary when the clinical picture is clear.

For most women with mature cystic teratoma, surgical excision provides a definitive diagnosis, affords relief of symptoms, and prevents torsion, rupture, and malignant transformation. Of surgical approaches, laparoscopy is appropriate, and route is selected as for other ovarian masses (p. 222). To prevent granulomatous peritonitis, the cyst can be enucleated over laparotomy sponges or an endoscopic bag to capture cyst spill (Kondo, 2010). Moreover, copious pelvic irrigation is a final surgical step if contents spill. In the past, the opposite ovary was explored because of the high frequency of bilateral lesions. However, given the accuracy of current sonographic imaging, this practice is no longer indicated for a normal-appearing contralateral ovary (Comerci, 1994).

Most of these masses are surgically removed, but a few studies support only surveillance. Especially those desiring future fertility, premenopausal women with cysts measuring <6 cm and with a confident diagnosis are reasonable potential candidates (Hoo, 2010; Pascual, 2017). These studies document slow tumor growth that averages <2 mm/year. If not removed, sonography is recommended every 6 to 12 months initially (Levine, 2010).

SOLID OVARIAN MASSES

Completely solid ovarian masses typically are benign. That said, these masses are still removed because of the inability to exclude malignancy in these tumors. Ovarian tumors that may present as a solid masses include: sex cord–stromal tumors, Krukenberg tumor, ovarian leiomyoma and leiomyosarcoma, carcinoid, primary lymphoma, and transitional cell tumors, also called Brenner tumors (Figs. 10-7 and 10-8). The most common solid tumors are fibromas or fibrothecomas, both typically benign stromal tumors and discussed in Chapter 36 (p. 767).

Solid adnexal masses may also represent nonneoplastic conditions. Ovarian remnant syndrome and ovarian retention syndrome stem from persistent functional ovarian tissue following surgery. These conditions most commonly cause pain and are discussed in Chapter 12 (p. 264). Rarely, congenital accessory ovaries may confuse sonographic findings and are discussed in Chapter 19 (p. 425).

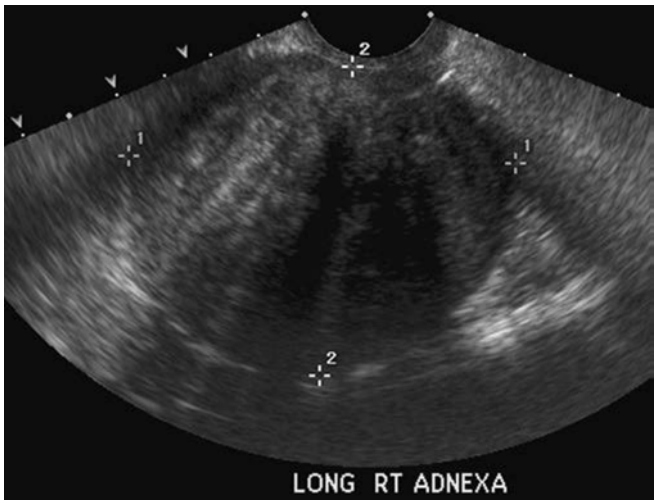

FIGURE 10-7 Transvaginal sonogram of a benign ovarian fibroma.

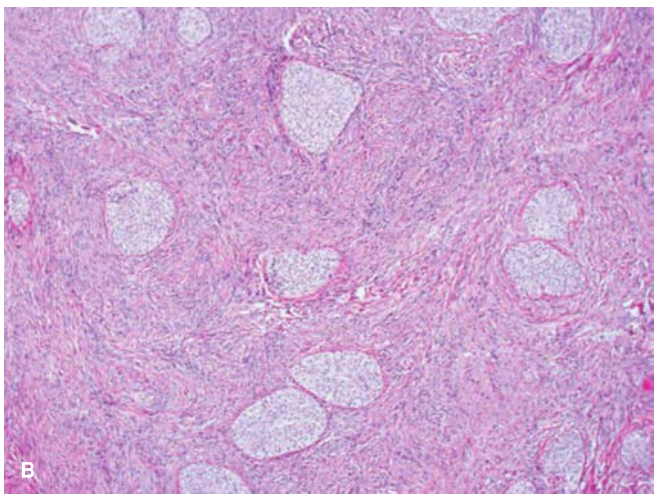

FIGURE 10-8 Photographs of a Brenner tumor following oophorectomy. **A.** A well-circumscribed, tan, rubbery mass with a smooth to slightly bosselated cut surface is characteristic. During preparation of this specimen for histologic assessment, black ink was applied to the external surface of the mass to allow identification of inner and outer surfaces during microscopic evaluation. **B.** Within densely fibrous stroma, sharply demarcated nests of transitional-type epithelial cells are found. These epithelial cells have prominent cell borders, lightly eosinophilic cytoplasm, and oval nuclei, without atypia or mitotic activity. (Reproduced with permission from Dr. Jason Mull.)

ADNEXAL TORSION

Torsion involves the twisting of adnexal components. Most often, the ovary and fallopian tube rotate as a single entity. Infrequently, an ovary may alone turn about its mesovarium, and rarely a fallopian tube twists alone about the mesosalpinx. Last, paraovarian mass may rotate independently and not involve the tube or ovary. Normal adnexa can twist, but in 50 to 80 percent of cases unilateral ovarian masses are identified (Nichols, 1985; Warner, 1985). Adnexal torsion accounts for 3 percent of gynecologic emergencies. Although this most commonly occurs during the reproductive years, postmenopausal women also can be affected. A disproportionate number of cases of adnexal torsion develop during pregnancy, and these compose 20 to 25 percent of all torsion cases.

Adnexal masses that possess greater mobility have greater torsion rates. Congenitally long uteroovarian ligaments create excessively mobile mesovaria and may raise the risk for even normal adnexa. Similarly, pathologically enlarged ovaries with a diameter >6 cm will typically rise from the true pelvis. Without these bony confines, mobility and torsion risk are increased. Accordingly, the highest rates of torsion are in adnexal masses measuring 6 to 10 cm (Houry, 2001). Torsion of the adnexa more commonly involves the right adnexa, likely because mobility of the left ovary is limited by the sigmoid colon (Hasiakos, 2008).

Two key points assist in initially maintaining blood flow to the involved adnexal structures despite twisting of their vascular pedicles. First, adnexa are supplied from the respective adnexal branches of both the uterine and ovarian vessels. During torsion, one of these, but not the other, may be involved. Second, although low-pressure veins draining the adnexa are compressed by the twisting pedicle, high-pressure arteries initially resist compression. As a result of this continued inflow but arrested egress of blood, the adnexa become congested and edematous but do not infarct. Consequently, torsion cases can often be conservatively managed at the time of surgery. With continued stromal swelling, however, arteries may become compressed, leading to infarction and necrosis that necessitate adnexectomy. Grossly, twisted adnexa are enlarged and often appear hemorrhagic (Fig. 10-9).

Diagnosis

Classically, the woman with adnexal torsion complains of sharp lower abdominal pain with sudden onset that worsens intermittently over several hours. The pain usually is localized to the involved side, with radiation to the flank, groin, or thigh. Low-grade fever suggests adnexal necrosis. Nausea and vomiting frequently accompany the pain.

Lack of clear physical findings can make diagnosis difficult. An adnexal mass may not be palpable, and during its early stages, significant discomfort may not be elicited during examination. Sonography plays an essential role. However, sonographic findings can vary widely depending on the degree of vascular compromise, the characteristics of any associated intraovarian or intratubal mass, and the presence or absence of adnexal hemorrhage. Sonographically, torsion may mimic

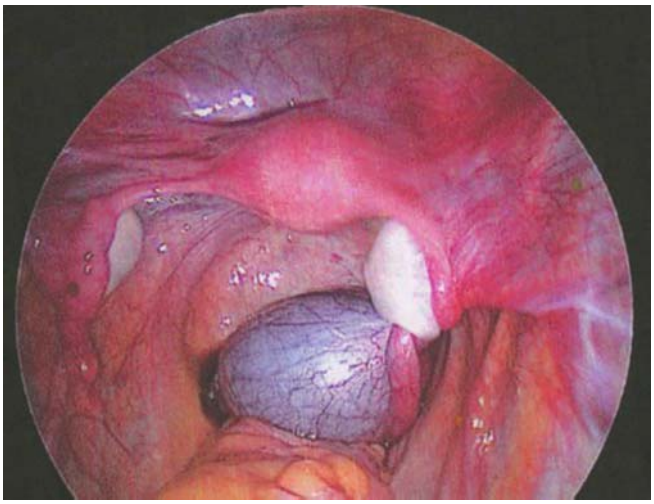

FIGURE 10-9 Laparoscopic photograph of adnexal torsion shows twisting of the fallopian tube and adjacent cyanotic paratubal cyst, which is distinct from the ovary. (Reproduced with permission from Dr. Ellen Wilson.)

ectopic pregnancy, tuboovarian abscess, hemorrhagic ovarian cyst, and endometrioma. Accordingly, rates of correct diagnosis range from 50 to 75 percent (Graif, 1984; Mashiach, 2011).

Despite these limitations, specific findings have been described. First, multiple follicles rimming an enlarged ovary reflect ovarian congestion and edema described earlier. The twisted pedicle may also appear as a bull's-eye target, whirlpool, or snail shell, that is, a rounded hyperechoic structure with multiple, inner, concentric hypoechoic rings. In affected women, application of color Doppler may show disruption of normal adnexal blood flow. However, in some cases, incomplete or intermittent torsion may variably display both venous and arterial flow. Thus, disruption of vascular flow is highly suggestive of torsion. However, torsion should not be discounted on the basis of a normal Doppler study alone, especially with clinically suggestive signs and symptoms.

Last, CT or MR imaging is usually not required. These may be helpful in complicated cases or in those with ambiguous clinical presentation such as seen with incomplete or chronic torsion (Rha, 2002).

Management

Salvage of the involved adnexa, resection of any associated cyst or tumor, and indicated oophoropexy are treatment goals. Importantly, rapid operative intervention is believed to improve the likelihood of ovarian conservation (Rossi, 2012; Rousseau, 2008). Findings of adnexal necrosis, rupture with significant hemorrhage, or suspicion of malignancy, however, may necessitate removal of adnexal structures. Salpingo-oophorectomy is reasonable in postmenopausal women with ovarian torsion.

Torsion may be evaluated by laparoscopy or laparotomy. Previously, adnexectomy was usually done to avoid possible thrombus release and subsequent embolism during untwisting. Evidence does not support this. McGovern and coworkers (1999) reviewed nearly 1000 cases of torsion and found the rare occurrence of pulmonary embolism in only 0.2 percent. These cases of embolism were associated with adnexal excision, and none were linked to untwisting of the pedicle. In a study of 94 women with adnexal torsion, Zweizig and associates (1993) reported no increased morbidity in women undergoing untwisting of the adnexa compared with those undergoing adnexectomy.

For these reasons, detorsion of the adnexa is generally recommended. Within minutes following untwisting, congestion is relieved, and ovarian volume and cyanosis typically diminish. That said, a persistently black-bluish ovary is not pathognomonic for necrosis, and the ovary may still recover. Cohen and colleagues (1999) reviewed 54 cases in which adnexa were preserved regardless of their appearance following detorsion. They reported functional integrity and successful subsequent pregnancy in almost 95 percent. Bider and coworkers (1991) observed no increased postoperative infectious morbidity in cases similarly managed. Because adnexal necrosis may still occur, conservative management requires postoperative vigilance for fever, leukocytosis, and peritoneal signs.

Following detorsion, management of the adnexa is individualized. Specific ovarian lesions ideally are excised for pathologic diagnosis of the original mass and to prevent repeat torsion. However, cystectomy in a hemorrhagic, edematous ovary may be technically difficult. Therefore, some recommend cystectomy if the mass persists for 6 to 8 weeks after primary intervention (Adeyemi-Fowode, 2019; Rody, 2002).

The retorsion rate among fertile women was 28 percent in one review of 38 publications (Hyttel, 2015). To minimize these rates, unilateral or bilateral oophoropexy may be considered (Djavadian, 2004; Kives, 2017). Techniques to secure the ovary vary. These include shortening of the uteroovarian ligament with a running accordion stitch through the ligament. Instead, the ovary or the uteroovarian ligament can be sutured to the posterior aspect of the uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010; Weitzman, 2008). However, the effects of this positioning on ovum uptake and later fertility are unclear.

Management during pregnancy does not differ. However, if the corpus luteum is removed, progestational support is recommended until 10 weeks' gestation to maintain the pregnancy. Suitable progesterone replacement regimens include: (1) micronized vaginal progesterone (Prometrium) 200 mg twice or three times daily; (2) 8-percent progesterone vaginal gel (Crinone) 90 mg once or twice daily; (3) progesterone vaginal insert (Endometrin) 100 mg twice or three times daily; (4) micronized oral progesterone (Prometrium) 200 mg orally twice or three times daily; (5) progesterone in oil (compounded in a specialty pharmacy) 50 to 100 mg daily intramuscular injection; or (6) intramuscular 17-hydroxyprogesterone caproate 150-mg weekly injections.

PARAOVARIAN MASSES

Most paratubal/paraovarian cysts are not neoplastic and are either distended remnants of the paramesonephric duct or mesothelial inclusion cysts (Fig. 10-10). One autopsy series cited a rate of approximately 5 percent of adnexal cysts (Dorum, 2005). The most common paramesonephric cyst is the *hydatid*

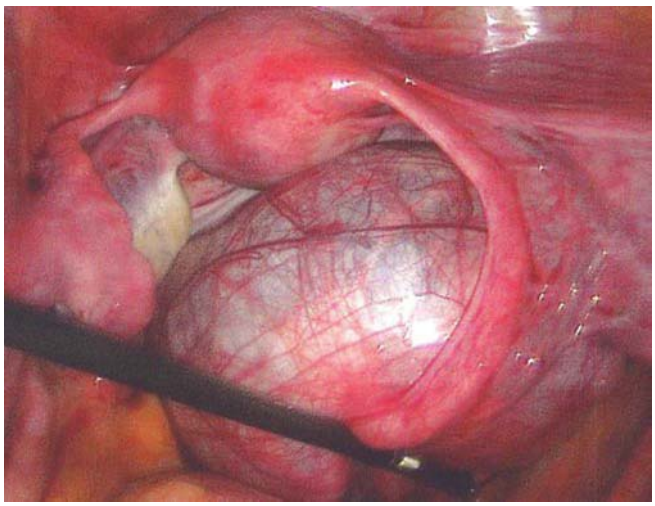

FIGURE 10-10 In this laparoscopic photograph, a large right paratubal cyst lies between its adjacent and outstretched fallopian tube and the uterus. (Reproduced with permission from Dr. Ellen Wilson.)

of Morgagni, which is pedunculated and typically dangles from one of the fimbria. Neoplastic paraovarian cysts are rare and histologically resemble tumors of ovarian origin. They are usually cystadenomas or cystadenofibromas and rarely malignant (Korbin, 1998).

Paratubal and paraovarian cysts are most commonly identified in asymptomatic women during surgery or sonography for other gynecologic problems. If symptoms develop, they mimic those of ovarian cysts. They are infrequently associated with complications such as hemorrhage, rupture, or torsion (Genadry, 1977).

Transvaginal sonography is often used as a primary evaluation tool for symptomatic women, and most of these cysts have thin, smooth walls and anechoic centers. However, sonography and MR imaging have limitations in differentiating between paraovarian and ovarian pathology (Ghossain, 2005). Thus, many women are managed as if diagnosed with a comparable ovarian cyst. When surgically managed, cystectomy or, less frequently, drainage and fulguration of the cyst wall are performed. When small and noted as an incidental intraoperative finding, these are generally excised, although this is not an evidence-based practice.

Of solid paraovarian tumors**,** leiomyomas are the most common and have pathophysiology identical to those within myometrium. Infrequently, congenital anomalies such as an accessory or supernumerary ovary, rudimentary uterine horn, or pelvic kidney may present as a pelvic mass with or without symptoms. One rare solid paraovarian tumor arises as a remnant of the wolffian duct and has been termed the *female adnexal tumor of probable wolffian origin* (Devouassoux-Shisheboran, 1999). Most reported cases are benign, but a few malignancies have been noted (Hong, 2018). These mirror the path of the embryologic wolffian duct and develop within the broad ligament or along the mesosalpinx (Kariminejad, 1973). Other rare paraovarian solid tumors include sarcomas, lymphoma, adenocarcinoma, pheochromocytoma, and choriocarcinoma.

Most paraovarian solid tumors are asymptomatic and identified on routine pelvic examination. Occasionally, there is unilateral pelvic and abdominal pain. Sonography and MR imaging are used to visualize these masses, although accurate differentiation between benign and malignant lesions is typically not possible. Thus, most solid masses are surgically removed.

FALLOPIAN TUBE PATHOLOGY

Hydrosalpinx

Fallopian tube neoplasms are rare, and most fallopian tube masses involve ectopic pregnancy or the sequelae of pelvic inflammatory disease (PID). Of these, hydrosalpinx is a chronic cystic swelling of the fallopian tube that forms following distal tubal obstruction. Causes include PID and endometriosis and rarely fallopian tube cancer. Grossly, the fine fimbria and tubal ostia are obliterated and replaced by a smooth, clubbed end (Fig. 10-11). The ballooned, thin walls of the elongated tube are translucent, and the tube is typically distended with a clear serous fluid. The ipsilateral ovary may be adhered to the hydrosalpinx.

Hydrosalpinx may be found in asymptomatic women during pelvic examination or imaging done for other indications. Some women note infertility or chronic pelvic pain. The differential diagnosis mimics that for other cystic pelvic lesions. In general, no laboratory test is helpful, and serum CA125 level testing results for presumed ovarian malignancy are typically normal.

Sonographic interrogation shows a thin-walled, cystic fusiform structure with incomplete septa and anechoic contents (Fig. 10-12A). In some, multiple hyperechoic mural nodules measuring 2 to 3 mm arch around the inner circumference of the tube to create the *beads on a string* sign. These nodules represent fibrotic endosalpingeal folds. Performed for fertility evaluation, hysterosalpingography shows ballooned, clubbed fallopian tubes filled with contrast (see Fig. 10-12).

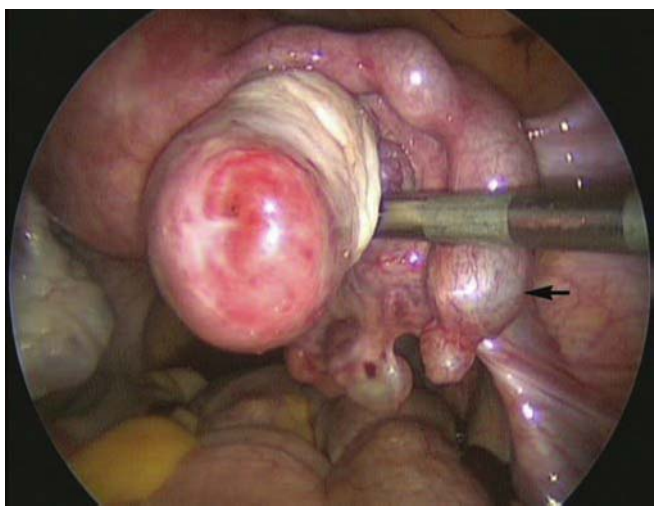

FIGURE 10-11 Laparoscopic photograph of a hydrosalpinx. Note the thin-walled ballooned fallopian tube and its clubbed end (*arrow*) draped around the blunt probe. A typical corpus luteum cyst is seen at the distal end of the ovary. (Reproduced with permission from Dr. Karen Bradshaw.)

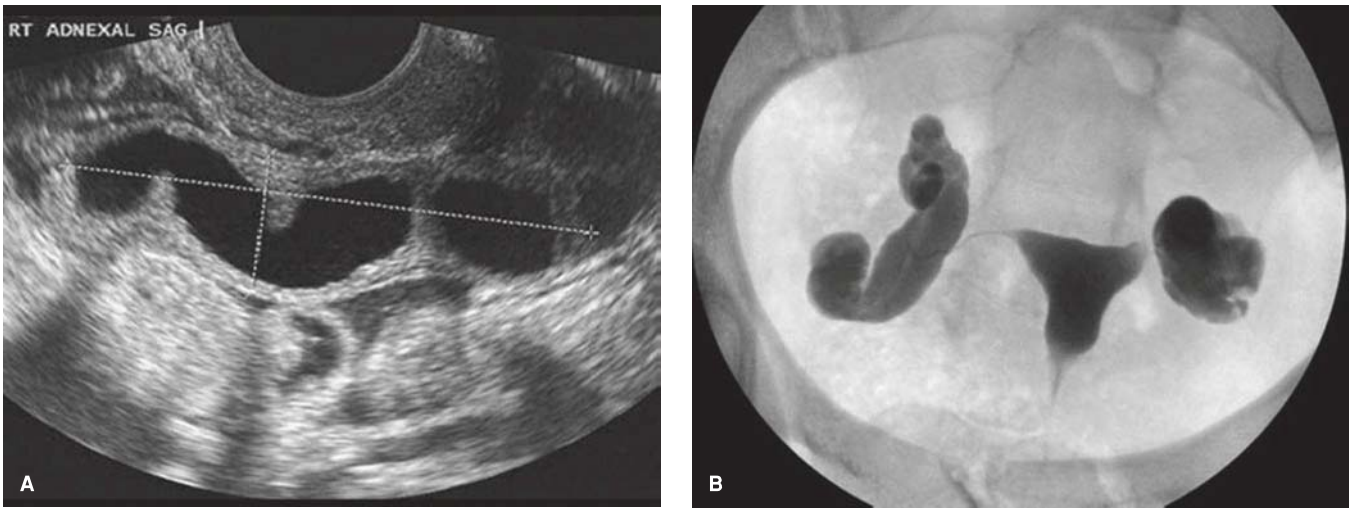

FIGURE 10-12 A. Transvaginal sonogram of a hydrosalpinx. Incomplete septa, which are folds of the dilated tube, are seen within this fusiform, fluid-filled structure. (Reproduced with permission from Dr. Elysia Moschos.) **B.** Hysterosalpingogram shows bilateral ballooned hydrosalpinges with clubbed ends. (Reproduced with permission from Dr. Kevin Doody.)

Management varies depending on the conviction of diagnosis, desire for future fertility, and associated symptoms. In asymptomatic women who have completed childbearing, and in whom the sonographic evidence supports the diagnosis of hydrosalpinx, expectant management is typical. In those with pelvic pain or infertility, or in whom the diagnosis is uncertain, diagnostic laparoscopy is often chosen.

For women not wishing to preserve fertility, laparoscopic treatment may include lysis of adhesions and salpingectomy. Conversely, in women who desire fertility, surgical intervention depends on the degree of tubal damage. As the degree of tubal distortion increases, fertility rates decline. In women with mild tubal disease, laparoscopic neosalpingostomy has resulted in 80-percent pregnancy rates and is a reasonable approach (Fig. 21-7, p. 460) (Milingos, 2000; Schlaff, 1990).

In those with severe tubal disease, in vitro fertilization (IVF) may offer a greater chance at conception. However, of infertile women undergoing IVF, women with hydrosalpinges have approximately half the pregnancy rate of those without dilated tubes (Camus, 1999; Zeyneloglu, 1998). The explanation is unclear, and theories include toxic hydrosalpinx fluid, lowered growth factor concentrations, and mechanical flushing of embryos by excess fluid (Loutradis, 2005; Lu, 2013; Strandell, 2002). If hydrosalpinges are resected prior to IVF, subsequent rates of pregnancy, implantation, and live births are improved (Johnson, 2010; Strandell, 1999). The American Society for Reproductive Medicine (2015) recommends such surgery prior to IVF.

Benign Neoplasms

These are rare in the fallopian tube. The most common benign tumor is mesothelioma, which is found in <1 percent of hysterectomy specimens (Pauerstein, 1968). Previously termed adenomatoid tumors, these 1- to 2-cm, well-circumscribed solid nodules arise in the tubal wall (Salazar, 1972). Tubal leiomyomas are uncommon and derive from the smooth muscle of the tubal muscularis, from the broad ligament, or from vessels in either location.

The epithelium of the fallopian tube contains an intermixing of both ciliated and secretory cells. The secretory cell population increases with age, and cellular outgrowths can be seen histologically that contain only secretory cells (Li, 2013). These benign secretory cell outgrowths (SCOUTs) and their link to serous tubal intraepithelial carcinoma (STIC) and pelvic serous carcinoma are current research topics (Mehrad, 2010). These are described in Chapter 35 (p. 738).

Tuboovarian Abscess

This is an inflammatory mass involving the fallopian tube, ovary, and often surrounding structures. If an ovary adheres to the fallopian tube, but is still visually distinct, it is called a *tuboovarian complex*. In contrast, a *tuboovarian abscess* results from a complete breakdown of ovarian and tubal architecture such that the separate structures are no longer identified. Either is usually a consequence of PID, although occasionally endometritis and pelvic malignancy may be the generative source. Affected women usually have lower abdominal pain, fever, leukocytosis, and unilateral or bilateral adnexal masses. These abscesses and their management are more fully discussed in Chapter 3 (p. 70).

CHAPTER 11

Endometriosis

EPIDEMIOLOGY 233
PATHOPHYSIOLOGY 233
CLASSIFICATION 236
SYMPTOMS 236
DIAGNOSTIC EVALUATION 239
TREATMENT 240
MEDICAL TREATMENT OF PAIN 242
SURGICAL TREATMENT OF PAIN 245
ENDOMETRIOSIS-RELATED INFERTILITY 247
REFERENCES 247

Endometriosis is a common gynecologic condition in which endometrial tissue is present outside the uterine cavity. Endometrial tissue located within the myometrium is termed *adenomyosis* and is discussed in Chapter 9 (p. 213). With its molecular basis further elucidated, endometriosis now is seen more as a systemic disease, with the implants of endometriosis leading to an inflammatory response. Although some women with endometriosis may be asymptomatic, many others present with subfertility or various forms of chronic pelvic pain (CPP). Endometriosis often strikes women during their early career or schooling, and the long-term harm to professional or social development can be profound (Lamvu, 2019). As endometriosis is an estrogen-dependent disease, hormone-based treatment is a mainstay of therapy. However, if disease is unresponsive to medical management, surgery may be required.

EPIDEMIOLOGY

Approximately 10 percent of all reproductive-aged women are affected by endometriosis (Rogers, 2009). Given that many women with endometriosis are asymptomatic, the true prevalence is difficult to quantify. Imaging modalities of any pelvic compartment generally have low specificities (Wall, 2015). Thus, the "gold standard" diagnostic method is laparoscopy, with or without biopsy for histologic diagnosis (Dunselman, 2014). With this, the annual incidence of surgically diagnosed endometriosis is 1.6 cases per 1000 reproductive-aged women (Houston, 1987). In asymptomatic women, the prevalence of endometriosis ranges from 6 to 11 percent, depending on the population studied and diagnostic mode (Buck Louis, 2011; Mahmood, 1991). Among patients with infertility, endometriosis is more common, and prevalence rates lie between 20 to 50 percent. In those with CPP, it ranges from 40 to 50 percent (Balasch, 1996; Eskenazi, 2001; Meuleman, 2009). Nearly two thirds of adolescents undergoing diagnostic laparoscopy for pelvic pain have evidence of endometriosis (Janssen, 2013).

Of potential risk factors, lower body mass appears to positively correlate with endometriosis risk (Peterson, 2013; Shah, 2013). Early menarche, especially before age 14, carries increased risk for endometriosis. Similarly, nulliparas have a higher risk that likely is secondary to a greater number of ovulatory cycles (Missmer, 2004; Treloar, 2010; Vercellini, 2010). Evidence for racial differences in prevalence is conflicting (Jacoby, 2010).

PATHOPHYSIOLOGY

Pathogenesis

The definitive cause of endometriosis remains unknown, but several theories are proposed. The most favored one describes retrograde menstruation through the fallopian tubes (Sampson 1927; Tal, 2019). The refluxed endometrial fragments invade the peritoneal mesothelium and develop a blood supply for implant survival and growth. In correlation, women with outflow tract obstruction also have a high incidence of endometriosis, which often resolves following obstruction relief (Sanfilippo, 1986; Williams, 2014). Interestingly, >90 percent of women experience retrograde menstruation, yet only a small fraction develop endometriosis (Halme, 1984). Thus, factors that enhance menstrual remnant implantation or defects in its clearance may contribute.

Retrograde menstruation does not account for endometriosis found outside the peritoneal cavity. To account for this, hematogenous or lymphatic spread is a suggested mode. For example, the eutopic endometrium of affected women has greater lymphatic vessel density, which likely promotes endometrial tissue entry into lymphatic circulation (Jerman, 2015). This may explain the spread of endometriosis into pelvic sentinel lymph nodes, groin, and retroperitoneum of affected women (Moore, 1988; Mourra, 2015; Tempfer, 2011).

Still, cases of endometriosis after hysterectomy or in men defy both of these theories. One explanation is the derivation of endometriosis from stem cells (Batt, 2013; Du, 2007; Sasson, 2008). Specifically, progenitor cells inside the endometrium and multipotent bone marrow cells both contribute to endometrial growth (Hufnagel, 2015; Schwab, 2005). Progenitor cells can slough and seed ectopic endometrial sites (Pluchino,

2016; Li, 2018). One immunohistochemical study found that affected patients shed more of their endometrial basalis layer, which is the site of many progenitor cells (Leyendecker, 2002). Mesenchymal cells, likely from the bone marrow, also can spread and differentiate into ectopic endometrial implants. These mesenchymal cells may underlie many of the extraperitoneal implants seen in endometriosis (Figueira, 2011; Kao, 2011).

Instead, the coelomic metaplasia theory describes pluripotent cells within the parietal peritoneum that transform to tissue histologically identical to normal endometrium. Since the ovary and the progenitor of the endometrium, the müllerian ducts, are both derived from coelomic epithelium, such metaplasia may help explain endometriosis involving the ovary. This process also may underlie cases of endometriosis in those without menstruation, such as premenarchal girls, males treated with estrogen and orchiectomy for prostate cancer, and patients with müllerian agenesis (Marsh, 2005; Taguchi, 2012; Troncon, 2014).

One final theory suggests that müllerian remnants left along their embryonic path undergo abnormal differentiation leading to endometriosis. This is based upon histologic studies in female fetuses showing ectopic endometrium (Batt, 2013; Signorile, 2012).

Anatomic Sites

Endometriosis may develop anywhere within the pelvis and on other extrapelvic peritoneal surfaces. Most commonly, endometriosis is found in the dependent areas of the pelvis. The anterior and posterior cul-de-sacs, other pelvic peritoneum, the ovary, and uterosacral ligaments are frequently involved (Kennedy, 2005). Other sites are the rectovaginal septum, ureter, and bladder. Rarely, pericardium, surgical scars, and pleura may be affected. Implants may be superficial or they may be *deep infiltrating endometriosis (DIE)*, that is, infiltrative forms that involve vital structures such as bowel, bladder, and ureters. Some definitions of DIE also quantify invasion as >5 mm (Koninckx, 1994).

Ovarian endometriomas are frequent manifestations of endometriosis (Fig. 11-1). These smooth-walled, dark-brown ovarian cysts are filled with a chocolate-appearing fluid and may be uni- or multilocular. Their pathogenesis is unclear, yet three theories include invagination of ovarian cortex implants, coelomic metaplasia, and secondary involvement of functional ovarian cysts by endometrial implants located on the ovarian surface (Vignali, 2002). Continued menstruation into the cyst results in accumulation of old blood and cellular debris, forming the chocolate-appearing fluid.

Molecular Mechanisms

Endometriosis is an estrogen-dependent chronic inflammatory disease with aberrant growth of ectopic endometrial tissue. These ectopic endometrial implants show molecular differences from the eutopic endometrium of unaffected women. *Eutopic endometrium* is that which lines the uterine cavity. The aberrant molecular mechanisms in endometriosis are yet to be fully defined. However, suspected underpinnings include an implant

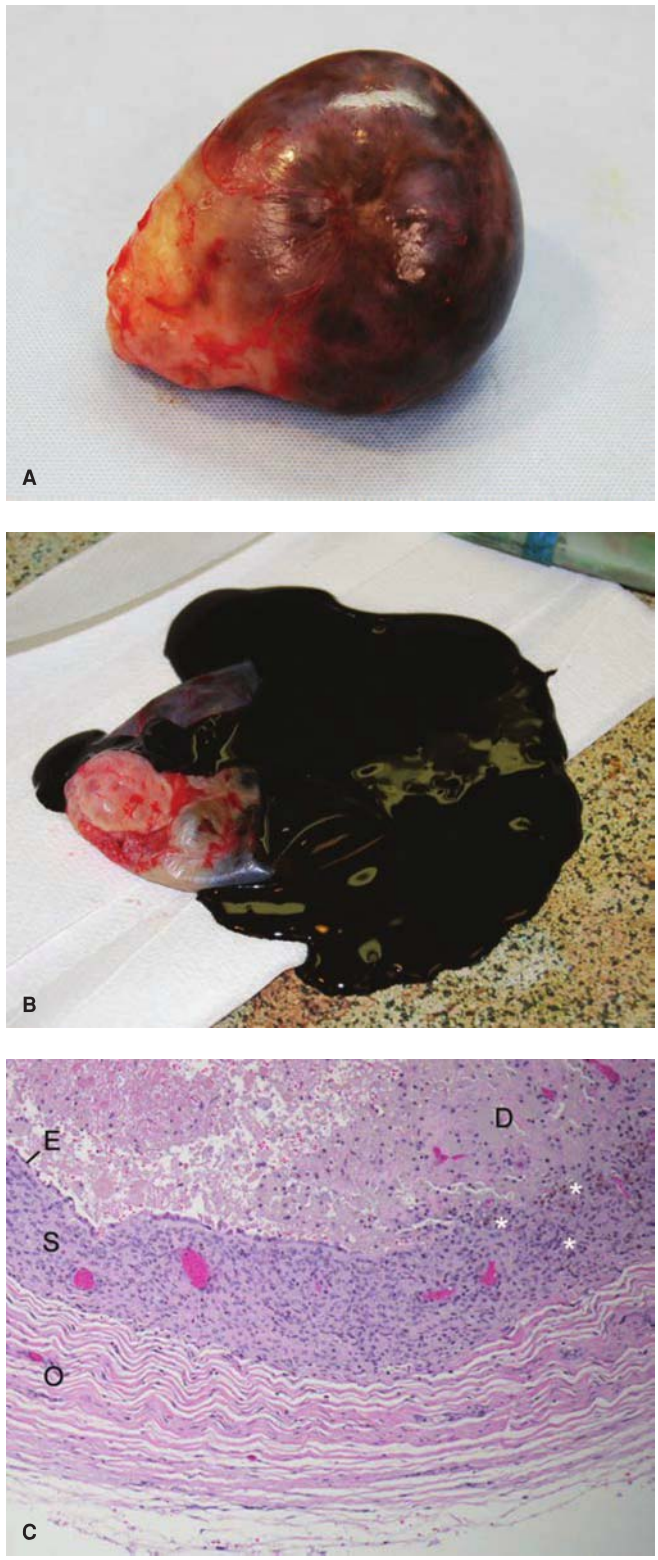

FIGURE 11-1 Endometrioma. **A.** Surgical specimen of an ovary containing an endometrioma. **B.** Dark, chocolate-like fluid had filled this cyst. (Photographs contributed by Dr. Roxanne Pero.) **C.** In ovarian endometriomas, endometrial-type epithelium (*E*) and subjacent stroma (*S*) line the cyst and are bordered peripherally by ovarian stroma (*O*). The golden brown pigment in the cyst wall (*asterisk*) is hemosiderin, indicating remote hemorrhage. Debris composed of necrotic and degenerating cells and remote hemorrhage occupies the interior of the cyst (*D*). It is the remote hemorrhage that confers the chocolate-like color to cyst fluid.

environment of estrogen dominance, estrogen dependence, and progesterone resistance; inflammation; escape from immune clearance; local invasion and neurovascularity development; and genetic predisposition.

Estrogen and Progesterone

Estrogen plays a causative role in endometriosis formation and is derived from multiple sources. First, most estrogen in women is produced directly by the ovaries. Second, peripheral tissues also produce estrogens through conversion of ovarian and adrenal androgens by the enzyme aromatase. Endometriotic implants express aromatase and 17β-hydroxysteroid dehydrogenase type 1, which are the enzymes responsible for conversion of androstenedione to estrone and of estrone to estradiol, respectively. Implants, however, are deficient in 17β-hydroxysteroid dehydrogenase type 2, which inactivates estrogen (Kitawaki, 1997; Zeitoun, 1998). Endometriotic stromal cells uniquely also express the full complement of genes in the steroidogenic cascade, which is sufficient to convert cholesterol to estradiol itself (Bulun, 2012). In sum, these enzymatic changes ensure that implants create an estrogenic environment. It also provides a rationale for aromatase inhibitor use in refractory clinical cases.

Normal progesterone effects are attenuated in endometriosis. This progesterone resistance is thought to stem from an overall low concentration of progesterone receptors within implants (Attia, 2000; Flores, 2018). Specifically, pathologic overexpression of estrogen receptor β in endometriosis suppresses estrogen receptor α expression. This diminishes estradiol-mediated induction of the progesterone receptor in endometriotic cells (Xue, 2007).

As one consequence of this resistance, survival of refluxed endometrium in affected women may be bolstered. Namely, normal endometrium has elevated levels of 17β-hydroxysteroid dehydrogenase type 2 in response to progesterone (Satyaswaroop, 1982). As a result, progesterone antagonizes the estrogen effects in normal endometrium during the luteal phase. Endometriosis, however, manifests a relative progesterone-resistant state, which prevents this antagonism in its implants (Patel, 2017).

Progesterone resistance may also enhance ectopic tissue implantation. First, mesothelium invasion can be aided by matrix metalloproteinases (MMPs). These are a group of collagenases implicated in endometrial turnover during normal menstruation. Progesterone represses MMP activity (Itoh, 2012). Thus, progesterone resistance within endometriotic implants may augment the MMP activity necessary for implant invasion.

Inflammation

Prostaglandin E_2 (PGE_2) is the most potent inducer of aromatase activity in endometrial stromal cells (Noble, 1997). Estradiol produced in response to the greater aromatase activity subsequently augments PGE_2 production (Gurates and Bulun 2003). This creates a positive feedback loop and potentiates the estrogenic effects. PGE_2 also augments MMP-2 activity, which can augment endometriosis angiogenesis (Jana, 2016).

In vitro inhibition of PGE_2 receptors, which are EP2 and EP4, decreases endometriotic lesion growth, angiogenesis, and innervation (Arosh, 2015). As a clinical correlate, nonsteroidal antiinflammatory drugs (NSAIDs) are used clinically to reduce prostaglandin formation and thereby decrease endometriosis-linked pain.

Immune System

With retrograde menstruation, refluxed menstrual tissue in most women is cleared by macrophages, natural killer (NK) cells, and lymphocytes. Accordingly, immune system dysfunction is one likely mechanism for endometriosis establishment (Seli, 2003). First, macrophages in greater numbers are found in the peritoneal cavity of affected women (Haney, 1981; Olive, 1985b). Although this increased population might logically act to suppress endometrial proliferation, macrophages in these affected women actually stimulate endometriotic tissue (Braun, 1994).

NK cells numbers are unaltered in the peritoneal fluid of affected women. However, their cytotoxicity against endometrium is diminished, especially in more advanced-stage endometriosis (Ho, 1995; Wilson, 1994). Several factors are suspected, but the exact reason for this decreased cytotoxicity is unclear.

Cellular immunity also is likely disordered in women with endometriosis. For example, the cytotoxic activity of T lymphocytes against autologous endometrium in affected women is impaired (Ulukus, 2005). Humoral immunity, which is B cell dependent, also is altered. IgG and IgA autoantibodies against endometrial and ovarian tissues are found in the sera and in cervical and vaginal secretions of affected women (Mathur, 1982; Odukoya, 1995). These results suggest that endometriosis has features similar to other autoimmune diseases.

Cytokines are involved in immune cell signaling. Numerous cytokines, especially interleukins, are identified in relevant tissues and are implicated in endometriosis pathogenesis (Arici, 1998; Mori, 1991; Tseng, 1996). Each of these cytokines produces or perpetuates a proinflammatory immune response.

Vascular endothelial growth factor (VEGF) is an angiogenic growth factor that is upregulated by estradiol in endometrial stromal cells and peritoneal fluid macrophages. Levels of this factor also are higher in the peritoneal fluid of affected women (McLaren, 1996).

Genetics

No mendelian genetic inheritance pattern has been identified for endometriosis. However, the greater incidence in first-degree relatives suggests a polygenic/multifactorial pattern. For example, in population studies, 4 to 8 percent of the female siblings or mothers of affected women had endometriosis (Dalsgaard, 2013). Studies also demonstrate concordance for endometriosis in monozygotic twin pairs (Saha, 2015; Treloar, 1999).

To assist with identifying candidate genes, researchers have used population-based genome-wide association study (GWAS). This method is founded on the principle that common diseases, such as endometriosis, are caused by genetic variants that are common themselves. From GWAS of endometriosis, several candidate genes and chromosomes have been identified for further investigation (Burney, 2013). In total, evidence from GWAS suggests that endometriosis inheritance is complex and likely polygenic.

Chronic Pain and Pain Sensitization

The exact mechanism for endometriosis-associated pain is not yet clear. Proinflammatory cytokines and prostaglandins released by endometriotic implants may be one source (Bulun, 2009). Nerve growth into endometriotic implants also has been implicated (Barcena de Arellano, 2011; McKinnon, 2012). Once an endometriotic lesion has been established, continued exposure of these sensory nerves to the implant's inflammatory environment can create central sensitization and CPP. The mechanism of central sensitization and its role in CPP is described fully in Chapter 12 (p. 254) (As-Sanie, 2013; Bajaj, 2003).

Moreover, in research studies, magnetic resonance (MR) imaging of brains of patients with CPP, either with and without endometriosis, shows consistent reduction in thalamic gray matter volume. However, no volume change is noted in the thalami of patients with endometriosis but no CPP (As-Sanie, 2012). Hypersensitization and expansion of pain sensory regions also is observed in patients with endometriosis and CPP (As-Sanie, 2013; Neziri, 2010). These findings suggest that the persistent pelvic pain of endometriosis may be inadequately treated by therapies that address the endometriotic implants alone.

CLASSIFICATION

The extent of endometriosis can vary widely between individuals. In an attempt to classify this, a scheme was developed by the American Society for Reproductive Medicine (1997) (Fig. 11-2). With this system, endometriosis on the peritoneum, ovaries, fallopian tubes, and cul-de-sac is scored during surgery. At these sites, points are assigned for disease surface area, degree of invasion, morphology, and extent of associated adhesions. Endometriotic lesions also are morphologically categorized as white, red, or black. In this system, endometriosis is classified as stage I (minimal), stage II (mild), stage III (moderate), and stage IV (severe).

Advantages of this scheme are its widespread implementation, its ease of use, and its four simple-to-comprehend stages. However, the system has limitations. It correlates poorly with infertility and pain symptoms (Guzick, 1997; Vercellini, 1996). This poor predictive ability stems in part from scores that are derived from subjective visual examination. Moreover, disease involving ureter, bowel, or other extrapelvic sites is not scored (Adamson, 2013). To address these shortcomings, other methods have been developed but are yet to be widely used. These include the ENZIAN staging system to better represent DIE and the Endometrial Fertility Index (EFI) to predict fertility in endometriosis patients (Adamson, 2010; Haas, 2011). The World Endometriosis Society (WES) established consensus statements concerning the roles of these three assessment tools (Johnson, 2017).

SYMPTOMS

Pain

Women with endometriosis may be asymptomatic. However, compared with unaffected women, they are much more likely to have subfertility or CPP (Ballard, 2008). Dysmenorrhea,

dyspareunia, and noncyclic pain are common pain manifestations. Less often, affected women may also note dyschezia (pain with defecation), dysuria, or abdominal wall pain (Schliep, 2015). The variability of implant location and inflammatory mediators help explain the differing pain manifestations.

To initially assess CPP, pain scoring tools such as the visual analogue scale (VAS) and the numerical rating scale (NRS) are options. These are shown in Figure 12-2 (p. 258) (Bourdel, 2015). Posttreatment scoring allows evaluation of treatment response.

Of pain types in endometriosis, dysmenorrhea typically precedes menses by 24 to 48 hours. Compared with primary dysmenorrhea, this pain is thought to be more severe, more progressive, and less responsive to NSAIDs and combination oral contraceptives (COCs) (Opoku-Anane, 2012). DIE also positively correlates with dysmenorrhea severity (Lafay Pillet, 2014). Although initially cyclic, pelvic pain may become constant because of ongoing fibrosis, scarring, and adhesion formation.

Endometriosis-associated dyspareunia often is related to rectovaginal septum, uterosacral ligament, or posterior cul-de-sac disease, although other involved sites can cause painful intercourse (Vercellini, 2007, 2012). Tension on diseased uterosacral ligaments during intercourse may trigger this pain (Fauconnier, 2002). Although some women with endometriosis describe a history of dyspareunia since coitarche, endometriosis-associated dyspareunia is suspected if pain develops after years of pain-free intercourse (Montagna, 2008).

Noncyclic CPP is another frequent symptom of endometriosis. Of women with CPP, approximately 33 percent are found to have endometriosis during laparoscopy (Howard, 2003). This percentage is even higher in adolescents with CPP (Janssen, 2013). As noted earlier, endometriosis stage often does not correlate with the pain severity (Fedele, 1992; Hsu, 2011; Vercellini, 1996). Greater positive correlation for pain is seen with DIE (Hsu, 2011; Porpora, 1999).

The site of chronic pain may vary according to the lesion location. With rectovaginal septum or uterosacral ligament involvement, pain may radiate to the rectum or lower back. Alternatively, pain radiating down the leg may reflect sciatic nerve involvement (Possover, 2011).

Women with endometriosis-related chronic pain may experience comorbid depression (Gambadauro, 2019). An initial depression screen described in Chapter 1 (p. 19) is suitable. Treatment options and indications for consultation are described in Chapter 14 (p. 302).

Infertility

The incidence of endometriosis in women with subfertility is 20 to 30 percent (Waller, 1993). Although wide variability is reported, patients with infertility appear to have a greater incidence of endometriosis than fertile controls (13 to 33 percent versus 4 to 8 percent) (D'Hooghe, 2003; Strathy, 1982). Furthermore, Matorras and colleagues (2001) noted an increased prevalence of more severe stages of endometriosis in women with infertility.

Adhesions are one intuitive explanation for endometriosis-related infertility. These may impair normal oocyte pick-up and transport by the fallopian tube. Beyond mechanical impairment, numerous subtle defects also appear to be involved. Such defects include perturbations in follicle development, ovulation, sperm function, embryo quality and development, and implantation (Macer, 2012; Stilley, 2012).

Concerning endometriosis stages, associations between infertility and milder forms of endometriosis are not robust (D'Hooghe, 1996; Schenken, 1980). However, an association is suggested by the differing prevalence of endometriosis between infertile and fertile women. For example, in one small study, women with minimal endometriosis had a 12-month cumulative pregnancy rate of 47 percent, which falls below that of normal fertile women (Rodriguez-Escudero, 1988). Additionally, a prospective cohort study demonstrated that women with minimal or mild endometriosis had a fecundity similar to that of those with unexplained infertility (Bérubé, 1998).

In moderate to severe endometriosis (stage III to IV), tubal and ovarian architecture are often distorted. As a result, impaired fertility would be expected. Few studies report fecundity rates in women with severe endometriosis. One investigation comparing mild, moderate, and severe endometriosis revealed a monthly fecundity rate of 8.7 percent in those with mild disease, 3.2 percent with moderate disease, and no pregnancies with severe disease (Olive, 1985a). In another, women with severe endometriosis undergoing in vitro fertilization (IVF) had poorer implantation and pregnancy rates compared with those with mild disease (Harb, 2013).

Symptoms from Specific Sites

Rectosigmoid Lesions

Defecatory pain develops much less often than other types of CPP in patients with endometriotic lesions on the rectosigmoid colon. Complaints may be chronic or cyclic, and they can be associated with constipation, diarrhea, or cyclic hematochezia (Roman, 2013). Thus, gastrointestinal causes of CPP also are entertained and excluded during evaluation (Chap. 12, p. 268). The origin of symptoms can be fixation of the rectum to adjacent anatomic structures or rectal wall inflammation.

Symptoms may also stem from DIE of the gastrointestinal tract, which complicates 5 to 12 percent of proven endometriosis cases. Bowel DIE predominantly involves rectosigmoid colon and much less so the small bowel, cecum, or appendix (Ruffo, 2014b). Lesions usually are confined to the subserosa and muscularis propria. Thus, colonoscopy offers poor diagnostic sensitivity (Milone, 2015). Rarely, more severe cases may involve the bowel wall transmurally and lead to intestinal obstruction or a clinical picture suggesting malignancy (Kaufman, 2011; Ruffo, 2014a).

For diagnosis, rectal DIE can be imaged by transvaginal sonography (TVS), and sensitivity approximates 73 to 80 percent. However, TVS techniques used for DIE have a learning curve, and these are predominantly performed at select tertiary care centers (Tammaa, 2014). MR imaging can clarify anatomy and degree of invasion, especially preoperatively (Bazot, 2009; Wall, 2015). For rectosigmoid DIE, MR imaging has a sensitivity and specificity of 92 and 96 percent, respectively (Bazot, 2017). However, most simple peritoneal lesions are

not visualized, and laparoscopy typically provides definitive diagnosis.

Without obstructing symptoms, women may be considered for conservative management with hormonal therapy. However, treatment is often surgical, and cases often warrant a surgeon skilled in bowel surgery. Variables such as anatomic site, DIE depth, lesion size, and number of foci influence surgical planning. Colorectal segment resection is rarely necessary but should be an available option depending on the extent of lesion invasion. Less invasive techniques that shave down the lesion without opening the rectum or that excise discrete nodules also are described (Alabiso, 2015; Wolthuis, 2014).

Urinary Tract Lesions

Endometriosis should be considered if urinary tract symptoms persist despite negative urine culture results. Symptoms such as dysuria, suprapubic pain, urinary frequency, urgency, and hematuria are more common with bladder involvement by endometriosis (Gabriel, 2011; Seracchioli, 2010). Costovertebral angle pain may reflect ureteral endometriosis with obstruction and hydronephrosis that can progress eventually to loss of kidney function (Knabben, 2015).

In one large series, the prevalence of urinary tract DIE was 2.6 percent (Antonelli, 2006). Of the 31 patients, 12 had bladder endometriosis, 15 had ureteral endometriosis, and four had both ureteral and bladder involvement. TVS has suitable accuracy for bladder DIE but, as expected, is less sensitive for ureteral disease (Exacoustos, 2014a). In unclear cases, MR imaging can add additional anatomic information. Cystoscopy with biopsy also can help clarify the diagnosis.

Treatment is either medical or surgical. If elected, surgery for bladder invasion typically involves partial cystectomy. Surgeries for ureteral involvement vary by disease severity and involved segment. Operations may include: (1) freeing the tethered ureter by ureterolysis, (2) segmental resection and primary reanastomosis, or (3) ureter reimplantation into the bladder (Seracchioli, 2010).

Anterior Abdominal Wall

Some individuals with abdominal pain can have anterior abdominal wall endometriomas. Most of these lesions develop in an abdominal scar after uterine surgery or cesarean delivery, whereas others form unrelated to prior operations (Fig. 11-3) (Ding, 2013). Pfannenstiel incisions are disproportionately affected. Implants usually are found within the subcutaneous layer, are palpable, and can variably involve the adjacent fascia. Less often, the rectus abdominis muscle is infiltrated (Mostafa, 2013). Diagnostic tools are employed variably, and abdominal wall sonography, computed tomography (CT), MR imaging, and fine-needle aspiration are diagnostic options. The decision to perform concurrent TVS typically is guided by whether CPP symptoms coexist.

In most instances, implants are surgically excised for pain relief and diagnosis. For small implants, preoperative imaging may not be needed. But with larger implants and concerns for fascial or rectus abdominis muscle involvement, CT or MR imaging is helpful. Images can guide surgery planning and the possible need for abdominal wall mesh placement (Ecker, 2014).

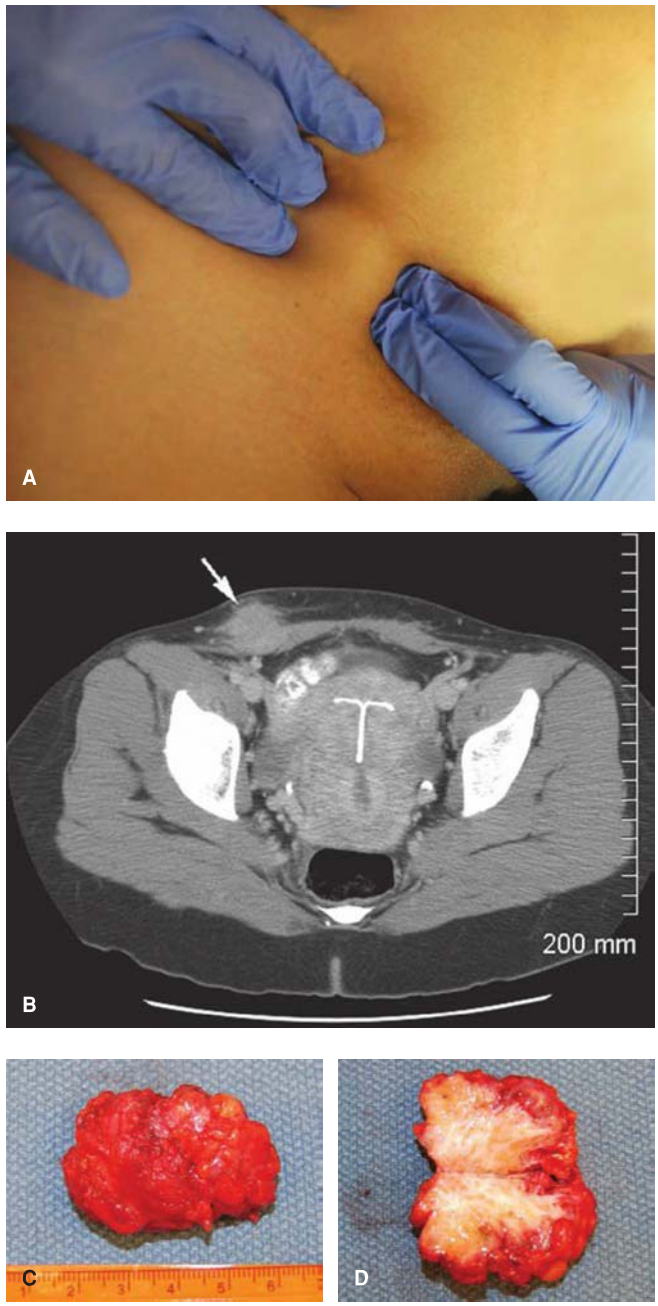

FIGURE 11-3 Endometriosis within a Pfannenstiel incision scar. **A.** Preoperative photograph delineates the borders of the mass. **B.** Computed tomography image shows a subcutaneous mass extending down to the anterior abdominal wall fascia on the left. **C.** Excised mass. **D.** Bivalved mass shows white fibrous scarring within yellow subcutaneous fat. Pathologic evaluation confirmed endometriosis. (Reproduced with permission from Dr. Christi Capet.)

Thoracic Lesions

Thoracic endometriosis defines implants inside the thoracic cavity that lead to symptoms described as menstrual or synonymously called *catamenial*. These include cyclic chest or shoulder pain, hemoptysis, or pneumothorax, which predominantly occurs on the right (Haga, 2014; Rousset-Jablonski, 2011; Tulandi, 2018). Chest CT is the preferred imaging modality (Rousset, 2014). For the case of catamenial pneumothorax, minimally invasive thoracoscopic surgery usually is indicated. This is often

coupled with postoperative gonadotropin-releasing hormone (GnRH) or progestin therapy identical to that for pelvic endometriosis treatment (Alifano, 2010). Depending on findings, hemoptysis may be treated hormonally or surgically.

DIAGNOSTIC EVALUATION

Physical Examination

Endometriosis is confined predominantly to the pelvis, and visual cues often are lacking. Exceptions include endometriosis within an episiotomy or other surgical scar (Koger, 1993; Zhu, 2002). Rarely, endometriosis may develop spontaneously within the perineum or perianal region (Watanabe, 2003). Occasionally, blue or red powder-burn lesions are seen on the cervix or the posterior vaginal fornix. These lesions can be tender or bleed with contact. In one study, 14 percent of patients diagnosed with DIE had endometriotic findings seen by speculum evaluation (Chapron, 2002).

During bimanual examination, pelvic organ palpation often reveals suggestive anatomic abnormalities. Uterosacral ligament nodularity and tenderness may reflect active disease or scarring along the ligament. An enlarged, cystic adnexal mass may be an ovarian endometrioma, which can be mobile or adhered to other pelvic structures. A retroverted, fixed, tender uterus and a firm, fixed posterior cul-de-sac are other findings. However, examination is generally inaccurate in assessing the extent of endometriosis, especially if the lesions are extragenital (Bazot, 2009). Last, rectal examination may reveal rectovaginal septum nodularity or tenderness.

Laboratory Testing

Although not specific for endometriosis, various tests are used to diagnose other causes of pelvic pain. Initially, a complete blood count (CBC), human chorionic gonadotropin assay, urinalysis and urine cultures, vaginal cultures, and cervical swabs may be collected to exclude infections or pregnancy complications. If urinary tract endometriosis is suspected, creatinine levels can assess renal function.

Numerous serum markers have been studied as possible indicators of endometriosis. Cancer antigen 125 (CA125) is an antigenic determinant on a glycoprotein that is found in fallopian tube epithelium, endometrium, endocervix, pleura, and peritoneum. This marker is used in ovarian cancer evaluation and surveillance. With endometriosis, levels can be elevated and positively correlate with disease severity (Hornstein, 1995a). Unfortunately, the assay has poor sensitivity in detecting mild endometriosis and appears to be a better diagnostic test for stage III or IV endometriosis (Mol, 1998; Santulli, 2015). Other suspected biomarkers include VEGF, thyroid stimulating hormone (TSH), and cytokines such as interleukin 6 (IL-6) or IL-8. However, these and many others appear not to provide suitable clinical accuracy (May, 2010).

Recently, microRNAs have been assessed for this diagnostic role. MicroRNAs are RNA oligonucleotides, typically 18 to 22 nucleotides long, that are essential for modulating gene expression (Bartel, 2009). Several microRNAs are differentially expressed in endometriosis and include miR-125b-5p and the let-7 family of microRNAs. In the future, these may serve as a noninvasive diagnostic tool.

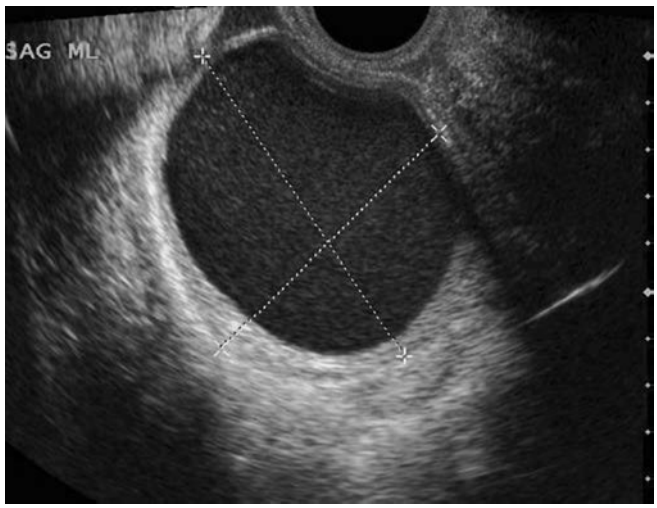

FIGURE 11-4 Transvaginal sonogram demonstrating ovarian endometrioma. A cyst with diffuse internal low-level echoes is seen.

Diagnostic Imaging

Many women with endometriosis present with CPP, and thus TVS is an initial imaging tool. TVS has suitable accuracy for detecting endometriomas and aids exclusion of other pelvic pain sources. However, imaging of superficial endometriosis or associated adhesions is inadequate (Wall, 2015).

For endometriomas, TVS sensitivity and specificity range from 64 to 90 percent and from 22 to 100 percent, respectively (Moore, 2002). An endometrioma classically is cystic with homogeneous, low-level internal echoes, often described as having "ground glass" echogenicity. Surrounding ovarian tissue is normal (Fig. 11-4). As such, these may have an identical appearance to hemorrhagic corpus luteum cysts. Reimaging 6 to 8 weeks later can help differentiate these two. Corpora lutea typically will resolve but endometriomas persist. Most endometriomas are unilocular, but one to four thin septations can be found (Van Holsbeke, 2010). Less typically, these cysts can display thick septations or be thick-walled. Also less often, echogenic wall foci that lack flow when color Doppler is applied can be seen and typically are depositions of blood (Bhatt, 2006). Color Doppler TVS often demonstrates pericystic, but not intracystic, flow. Much less commonly, endometriomas can be found in postmenopausal women. These cysts often are multilocular, in contrast to those in reproductive-aged women.

As noted previously (p. 237), TVS for DIE involving the bowel and bladder has suitable accuracy (Exacoustos, 2014a; Hudelist, 2011). That said, for the diagnosis of rectal endometriosis, TVS is highly operator dependent, and experience is often lacking (Dunselman, 2014). Thus, MR imaging may clarify anatomy for equivocal sonographic findings and offers superior resolution at soft tissue interfaces (Fig. 11-5) (Bazot, 2017). In some DIE cases, MR imaging can assist preoperative planning.

CT scanning plays a limited role in the evaluation of endometriosis because of its poor sensitivity for small implants and

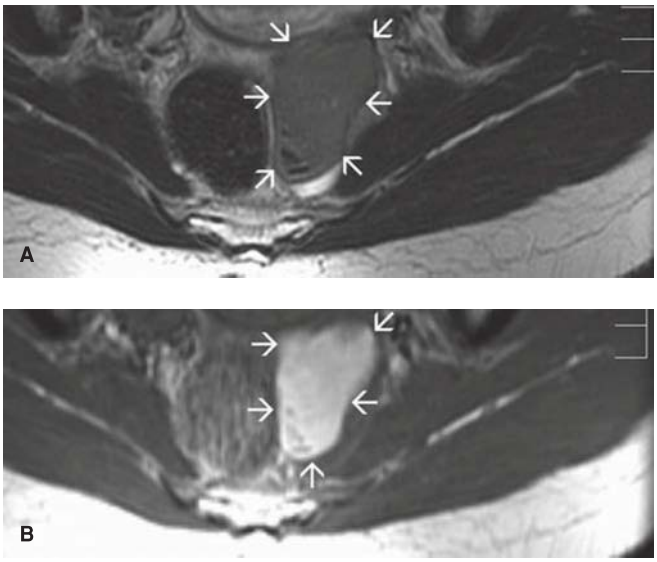

FIGURE 11-5 Magnetic resonance images of an endometrioma (*arrows*) just lateral to the rectum. **A.** Consistent with subacute blood, low-intensity signals are found on T2-weighted sequences. **B.** High-intensity signals are seen on T1-weighted sequences. (Reproduced with permission from Dr. Diane Twickler.)

plaques. Instead, CT is preferred for thoracic endometriosis and is suitable for abdominal wall endometrioma evaluation. In selected cases, CT may have a role in evaluating bowel or ureteral endometriosis (Exacoustos, 2014b).

Diagnostic Laparoscopy

Although imaging can add clinical information, laparoscopy is the primary method used for diagnosis (American College of Obstetricians and Gynecologists, 2018). Surgical findings are variable and may include discrete endometriotic lesions, endometrioma, or adhesions. Implants are typically found on pelvic organ serosa and pelvic peritoneum. Lesions are variably colored and can be red (red, red-pink, or clear), white (white or yellow-brown), and black (black or black-blue) (Fig. 11-6). White and red lesions most commonly correlate with the characteristic histologic findings of endometriosis (Jansen, 1986). Dark lesions are pigmented by hemosiderin deposition from trapped menstrual debris. Endometriotic lesions also can differ morphologically. They may be smooth blebs on peritoneal surfaces, holes or defects within the peritoneum, or flat stellate lesions whose points are formed by surrounding scar. Endometriotic lesions can be superficial or can deeply invade the peritoneum or pelvic organs.

Laparoscopic visualization of ovarian endometriomas has a sensitivity and specificity of 97 percent and 95 percent, respectively (Vercellini, 1991). Thus, cyst biopsy rarely is required for diagnosis.

Pathologic Analysis

Current guidelines do not require biopsy and histologic evaluation for endometriosis diagnosis. However, some suggest that relying solely on laparoscopic findings in the absence of histologic confirmation results in overdiagnosis (Buck Louis, 2011; Wykes, 2004). Specifically, the greatest discordance between laparoscopic and histologic findings is noted in scarred lesions (Walter, 2001). Histologic diagnosis requires both endometrial glands and stroma found outside the uterine cavity (Fig. 11-7). Histologic hemosiderin deposition also is common. The gross appearance of endometriotic lesions often suggests microscopic findings. For example, histologically, red lesions are frequently vascularized, whereas white lesions more often display fibrosis and few vessels (Nisolle, 1997).

In general, endometriosis is characterized by long delays until diagnosis. We believe that clinical diagnosis can speed the time to recognition and treatment (Agarwal, 2019; Taylor, 2018). Cyclic and progressive pelvic pain without other clear etiologies most commonly reflects endometriosis. Clinical diagnosis with initiation of therapy is reasonable.

TREATMENT

Therapy for endometriosis depends on a woman's specific complaints, symptom severity, location of lesions, goals for

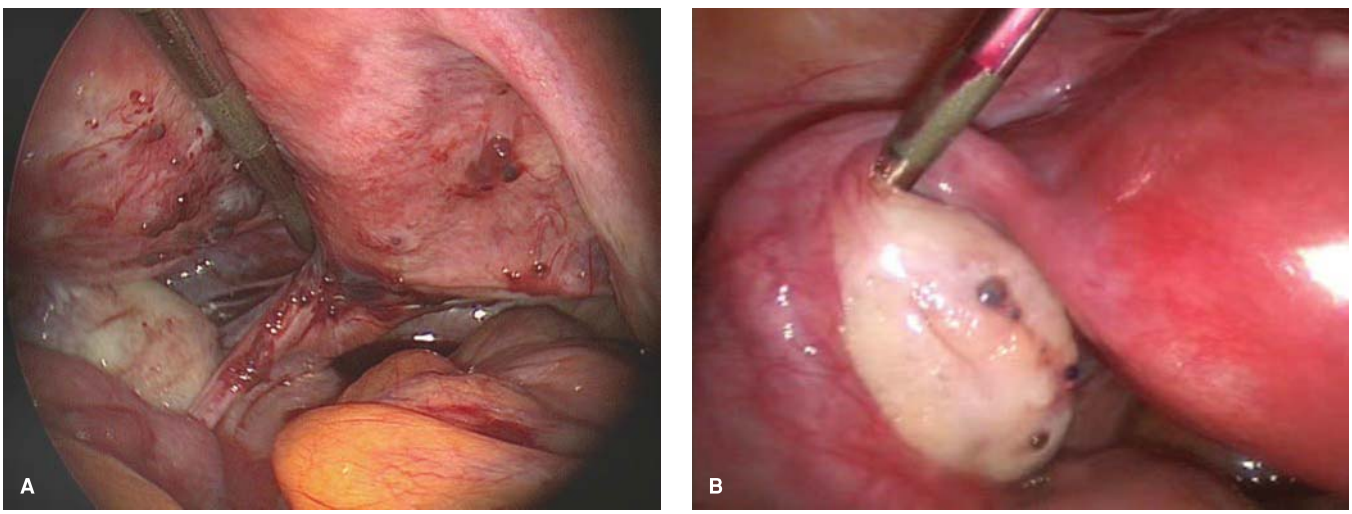

FIGURE 11-6 Endometriosis diagnosed during laparoscopy. **A.** Several red and clear endometriotic lesions seen on the pelvic peritoneum of the posterior cul-de-sac. **B.** Several brown-black lesions on the ovarian surface. (Reproduced with permission from Dr. David Rogers.)

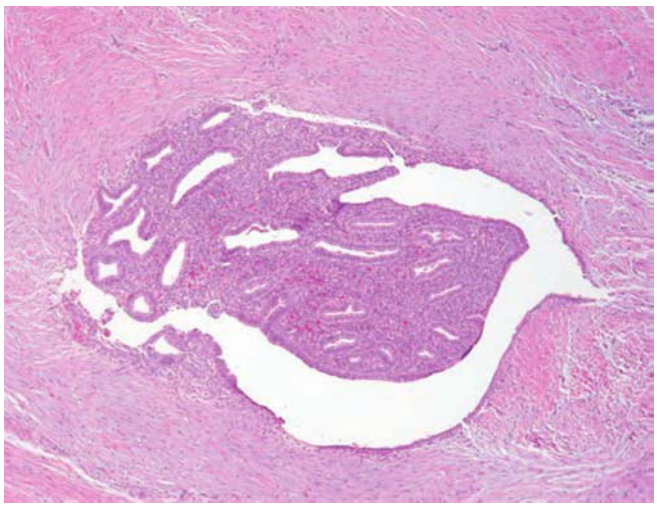

FIGURE 11-7 Endometriosis. This focus of endometrial glands and stroma was identified in the abdominal wall at the lateral aspect of a cesarean delivery scar. (Reproduced with permission from Dr. Kelley Carrick.)

treatment, and desire for future fertility (Fig. 11-8). If pain is prominent and conception is not currently desired, medical therapy usually is selected. Treatment strives to atrophy ectopic endometrium and lessen disease-associated inflammation. Agents include NSAIDs, COCs, oral progestins, androgens, GnRH agonists, GnRH antagonists, and aromatase inhibitors. For most, suitable initial regimens are NSAIDS combined with COCs or with a progestin. These agents may be initiated if endometriosis is suspected in a woman with CPP or may be started following diagnostic laparoscopy. Following laparoscopy, if initial therapy fails to control pain, switching to a different medication is suitable. With empiric therapy, if an initial agent(s) is ineffective, either diagnostic laparoscopy or medication change is indicated (American College of Obstetricians and Gynecologists, 2018). For those who fail to respond to progestin-containing options, a GnRH agent is reasonable. Although medical treatment improves pain, relapse rates are high with therapy discontinuation (Bozdag, 2015).

If infertility is the presenting symptom, fertility-preserving treatment without ovulation suppression will be required, as

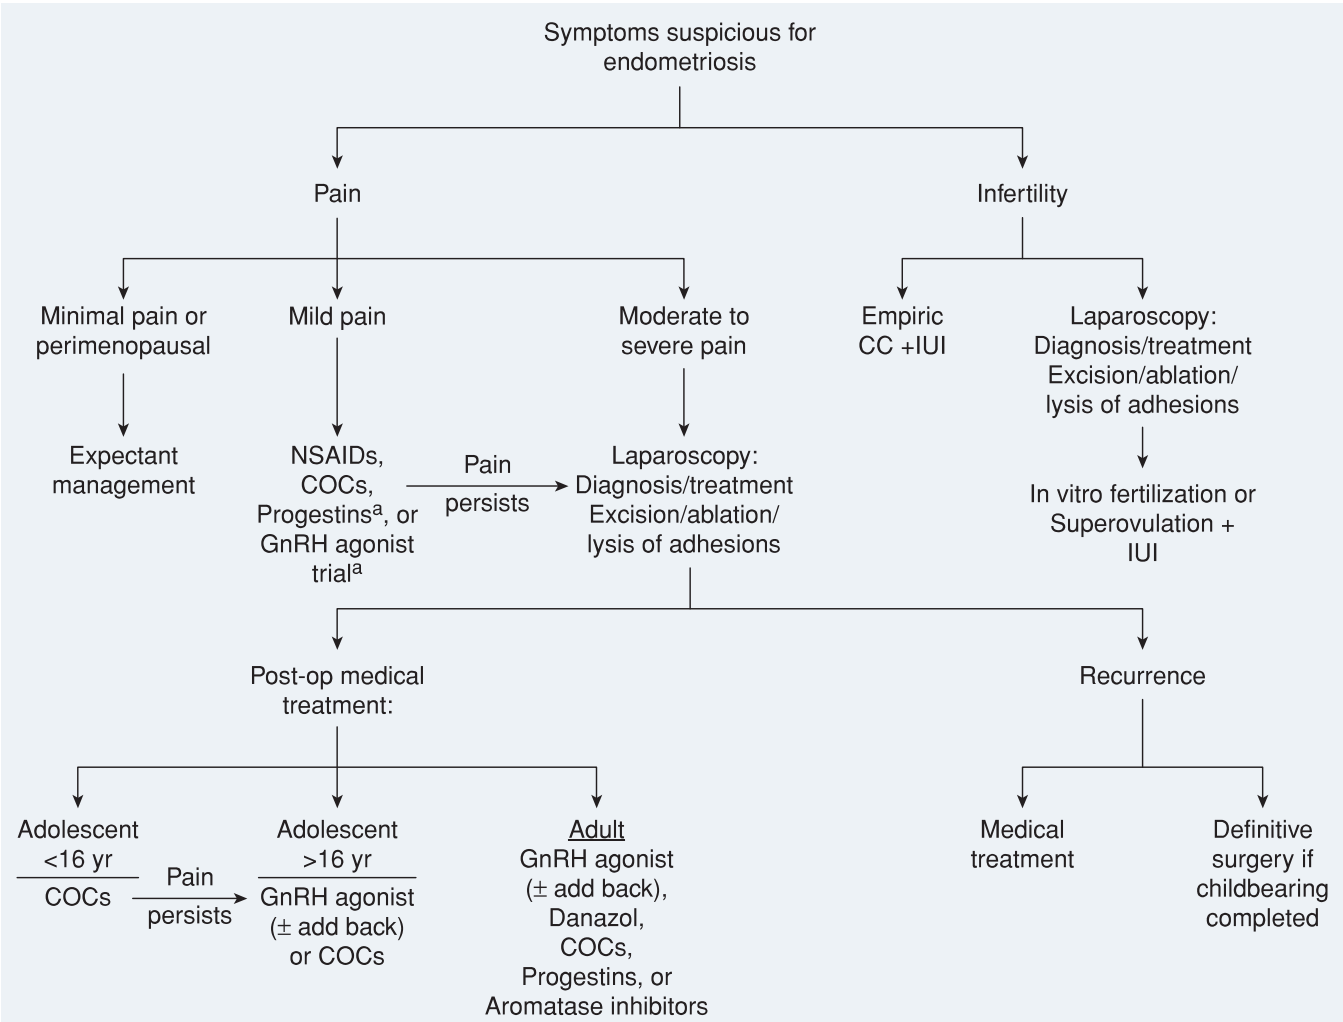

FIGURE 11-8 Diagnostic and treatment algorithm for women with presumptive or proven endometriosis. CC = clomiphene citrate; COCs = combination oral contraceptive pills; GnRH = gonadotropin-releasing hormone; IUI = intrauterine insemination; NSAIDs = nonsteroidal antiinflammatory drugs. [a]Agents not recommended for adolescents younger than 16 years.

outlined on page 274. In contrast, if the patient has severe, recalcitrant pain and has completed childbearing, definitive surgery may be indicated, as described on page 246.

Medical Treatment of Pain

Expectant Management

For many women, symptoms will preclude them from choosing expectant management. However, for those with mild symptoms or for asymptomatic women diagnosed incidentally, expectant management may be appropriate (Moen, 2002). Sutton and associates (1997) expectantly managed patients initially diagnosed by laparoscopy with minimal to moderate endometriosis. At second-look laparoscopy after 1 year, 29 percent of women had disease regression, 42 percent remained unchanged, and 29 percent had disease progression. Other investigators have shown similar rates of disease regression with expectant management (Thomas, 1987). These studies are confined to patients with minimal to moderate endometriosis. No well-designed trials have examined expectant management for severe disease.

Nonsteroidal Antiinflammatory Drugs

Both cyclooxygenase (COX)-1 and COX-2 enzymes promote synthesis of prostaglandins involved in the pain and inflammation associated with endometriosis. Specifically, endometriotic tissue expresses COX-2 at greater levels than eutopic endometrium (Cho, 2010). Accordingly, therapy aimed at lowering these prostaglandin levels helps alleviate endometriosis-associated pain. Indeed, NSAIDs often are first-line therapy in women with primary dysmenorrhea or CPP from suspected or known endometriosis. That said, study evidence supporting NSAIDs for this disease is scant and is extrapolated from efficacy data in primary dysmenorrhea (Kauppila, 1985; Marjoribanks, 2010).

The NSAIDs listed in Table 11-1 nonselectively inhibit both COX-1 and COX-2 enzymes. In contrast, selective COX-2 inhibitors specifically inhibit the COX-2 isoenzyme. Due to the cardiovascular risks with long-term use of selective COX-2 inhibitors, these medications are used at the lowest possible dose and for the shortest duration necessary (Jones, 2005). Thus, drugs in Table 11-1 are primarily selected.

Described earlier, central sensitization can lead to neuropathic pain in women with endometriosis. Multimodal approaches to chronic pain are discussed in Chapter 12 and listed in Table 12-5 (p. 263).

Combination Hormonal Contraceptives

These estrogen plus progestin-containing agents are a mainstay for the initial treatment of endometriosis-related pain. They inhibit gonadotropin release, decrease menstrual flow, and decidualize implants. As such, abundant study evidence supports use of COC pills or the contraceptive patch or ring to relieve endometriosis-related pain (Harada, 2008; Vercellini, 1993, 2010). These provide contraception and other noncontraceptive benefits, which are balanced against risks enumerated in Chapter 5 (p. 121).

COCs can be used conventionally in a cyclic regimen or may be used continuously without a break for withdrawal menses (American Society for Reproductive Medicine, 2014). The continuous regimen decreases the frequency of painful menses and improves CPP (Guzick, 2011). For endometriosis-related pain, monophasic COCs are preferred. Low-dose COCs (containing ≤20 μg ethinyl estradiol) are not superior to conventional-dose COCs for endometriosis treatment, but lower doses may lead to higher rates of breakthrough bleeding (Gallo, 2013).

Progestins

This family of hormones often is used for endometriosis therapy. Progestins antagonize the estrogenic effects on the endometrium. They cause initial decidualization and subsequent endometrial atrophy. For endometriosis treatment, oral progestins, depot progestins, or progestin-eluting intrauterine devices are options.

As supporting evidence, one randomized trial compared the effect of oral high-dose (100 mg) medroxyprogesterone acetate (MPA) daily given for 6 months and placebo. At second-look laparoscopy, partial or total resolution of peritoneal implants was noted in 60 percent of progestin-treated women compared with 18 percent of the placebo group. Furthermore, pelvic pain and defecatory pain were significantly reduced (Telimaa, 1987). In practice, MPA is prescribed in oral dosages ranging from 20 to 100 mg daily. Side effects of high-dose MPA included acne, edema, weight gain, and irregular menstrual bleeding.

Norethindrone acetate (NETA) is a 19-nortestosterone synthetic progestin. In one study, investigators administered an initial oral dosage of NETA, 5 mg daily, with increases of 2.5 mg daily until amenorrhea or a maximal dosage of 20 mg daily was reached. They found an approximately 90-percent reduction in dysmenorrhea and pelvic pain (Muneyyirci-Delale, 1998). Discussed later, NETA also is used as adjunct therapy with GnRH agents to blunt the bone loss linked with those drugs (DiVasta, 2015).

TABLE 11-1. Commonly Used Oral Nonsteroidal Antiinflammatory Drugs (NSAIDs) in the Treatment of Endometriosis-Associated Dysmenorrhea

Generic Name	Trade Name	Dosage
Ibuprofen	Motrin, Advil	400 mg every 4–6 h
Naproxen	Naprosyn, Aleve	500 mg initially, then 250 mg every 6–8 h
Naproxen sodium	Anaprox	550 mg initially, then 275 mg every 6–8 h
Mefenamic acid	Ponstel	500 mg initially, then 250 mg every 6 h
Ketoprofen	Orudis, Oruvail	50 mg every 6–8 h

Dienogest is another 19-nortestosterone synthetic progestin suitable for endometriosis. In one randomized study, it was significantly more effective than placebo for reducing endometriosis-associated pain when used orally at a dosage of 2 mg daily (Strowitzki, 2010a). Other trials show efficacy equivalent to that of GnRH agonists (Harada, 2009; Strowitzki, 2010b). Currently, this progestin alone is not available in the United States. It is, however, coupled with estradiol valerate in the Food and Drug Administration (FDA)-approved COC marketed as Natazia.

Alternatively, MPA may be given intramuscularly in depot form in a dosage of 150 mg every 3 months. In depot form, MPA may delay resumption of normal menses and ovulation and thus is less suitable for women contemplating imminent pregnancy. Subcutaneous formulation of MPA, marketed as Depo-SubQ Provera 104, also is effective (Schlaff, 2006).

Discussed in Chapter 5 (p. 127), the Depo-Provera package insert carries a "black box warning." This explains that prolonged DMPA use may result in bone mineral density (BMD) loss, that this loss is greater with increasing duration of use, and that the loss may not be completely reversible. Labeling recommends limiting use to 2 years unless other contraceptive methods are inadequate. Thus, the risks and benefits of treatment are weighed if contemplating long-term DMPA therapy. Bone density surveillance with dual energy x-ray absorptiometry (DEXA) scanning is not recommended (American College of Obstetricians and Gynecologists, 2019).

The levonorgestrel-releasing intrauterine system (LNG-IUS) (Mirena) delivers levonorgestrel directly to the endometrium and is approved for use up to 5 years. One small randomized trial that incorporated second-look laparoscopy showed improved endometriosis stage with both LNG-IUS and the comparator GnRH treatment. In other small randomized trials, the LNG-IUS provided improved symptoms compared against expectant management, DMPA, or GnRH agonists (Petta, 2005; Tanmahasamut, 2012; Vercellini, 2003b; Wong, 2010). The LNG-IUS also is effective for postoperative endometriosis suppression (Abou-Setta, 2013). However, in patients with bowel endometriosis, the LNG-IUS may be ineffective for symptoms (Hinterholzer, 2007). It likely also is less effective for other lesions types that are remote from the uterus. Contraindications to LNG-IUS use are listed in Chapter 5 (p. 115).

Intuitively, the Nexplanon implant that chronically releases the progestin etonogestrel might be considered for endometriosis. Data regarding its efficacy for this indication are limited. One small randomized study comparing this implant and DMPA reported comparable efficacy (Walch, 2009). A recent small prospective trial using a VAS score showed improved dysmenorrhea and dyspareunia at both 6 and 12 months compared with baseline scores (Sansone, 2018).

GnRH Agonists

Endogenous pulsatile release of GnRH prompts secretory activity of the gonadotropes within the anterior pituitary. Gonadotropin release from the pituitary then leads to ovarian steroidogenesis and ovulation. However, continuous, nonpulsatile GnRH administration results in pituitary desensitization and subsequent loss of ovarian sex steroid hormone production. These features allow pharmacologic use of GnRH agonists for endometriosis treatment. With loss of ovarian estradiol production, the hypoestrogenic environment removes the stimulation normally provided to the endometriotic implants and creates a pseudomenopausal state during treatment. In addition to this direct effect, GnRH agonists also reduce COX-2 levels in patients with endometriosis (Kim, 2009).

GnRH agonists are inactive if taken orally, but intramuscular (IM), subcutaneous (SC), and intranasal preparations are available. Leuprolide acetate (Lupron Depot) is available in a 3.75-mg monthly dose or an 11.25-mg 3-month dose, both given IM. Less frequently used GnRH agonists include goserelin (Zoladex) administered as a 3.6-mg monthly or a 10.8-mg 3-month SC depot implant; triptorelin (Trelstar) given as a 3.75-mg monthly IM injection; and nafarelin (Synarel) used in a 200-mg twice-daily nasal spray regimen. All of these except triptorelin carry specific FDA approval for endometriosis treatment.

Pain Improvement. Empirically, GnRH agonists may be used *prior to laparoscopy* in women with CPP and clinical suspicion of endometriosis. In one study, pain scores after 3 months of GnRH agonist treatment significantly declined compared with those after placebo (Ling, 1999). Subsequent laparoscopy revealed that 93 percent of these women had surgically diagnosed endometriosis. In suspected cases, depot leuprolide acetate may be used empirically *in lieu of laparoscopy* for satisfactory symptom improvement. However, an empiric GnRH trial is not routinely offered to patients younger than 16 years. GnRH agonist effects on long-term BMD have not been adequately studied in this age group.

In those with *surgically confirmed* endometriosis, numerous studies demonstrate the effectiveness of GnRH agonist therapy to improve pain symptoms (Brown, 2010). The GnRH agonists provide greater relief when administered for 6 months compared with 3 months (Hornstein, 1995b). As noted in the prior sections, GnRH agonists compares favorably with other drugs used for endometriosis treatment. In one metaanalysis of postoperative GnRH therapy, GnRH treatment reduced the endometriosis recurrence risk compared with placebo or expectant management (Zheng, 2016). Although GnRH agonist treatment is highly effective, its cost and side effects often favor trials of COCs or progestins first.

Add-Back Therapy. Concerns regarding the effects of prolonged hypoestrogenism preclude extended treatment with GnRH agonists alone. Hypoestrogenic symptoms include hot flashes, insomnia, reduced libido, vaginal dryness, and headaches. Moreover, both spine and hip BMD decline at 3 and 6 months of GnRH agonist therapy, with only partial recovery at 12 to 15 months after treatment (Orwoll, 1994).

Because of the greater osteoporosis risk and vasomotor symptoms, hormone therapy usually is added. Daily progestins or a low-dose estrogen plus progestin regimen is suitable and is termed *add-back therapy*. With this therapy, a GnRH agonist may be used longer than 6 months (American College of Obstetricians and Gynecologists, 2018). The goal of add-back therapy is to supply sufficient estrogen to minimize GnRH agonist side effects yet still maintain a hypoestrogenic state to suppress endometriosis. Barbieri (1992) explained that tissues have

varied sensitivity to estrogen, and a concentration of estrogen that will partially prevent bone loss may not stimulate endometrial growth. This "estrogen threshold" has not been established but is thought to approximate 30 to 40 pg/mL of estradiol.

Several regimens appear equally effective (Wu, 2014). In one 12-month study, NETA, 5 mg orally daily, with or without conjugated equine estrogen (Premarin) 0.625 mg orally daily, provided extended pain relief and preserved BMD (Hornstein, 1998). Another regimen of 25-µg transdermal estradiol plus daily 5 mg oral MPA showed that GnRH remained effective in reducing endometriosis pain (Edmonds, 1996). Traditional COCs also may be used effectively as add-back agents.

The extent of BMD decline has been evaluated with add-back therapy. Although bone loss was noted in all patients undergoing GnRH agonist treatment, the extent of loss was far lower or absent in the add-back group (Edmonds, 1994). Quality of life also is improved with add-back therapy (Zupi, 2004).

Ideally, this therapy is initiated simultaneously with the GnRH agonist. Little benefit is gained by deferring add-back therapy, and patients who receive add-back concurrently with agonist therapy have less bone loss (Al-Azemi, 2009; Kiesel, 1996). Pain relief is identical to those using GnRH agonist alone. Supplemental calcium as a 1000-mg total daily dose is recommended along with add-back regimens (American College of Obstetricians and Gynecologists, 2018).

GnRH Antagonists

GnRH antagonists are a newer category of GnRH analogues capable of suppressing gonadotropin production. Unlike GnRH agonists, GnRH antagonists do not produce an initial release or *flare* of gonadotropins. Thus, suppression of gonadotropins and of sex steroid hormones is immediate.

Elagolix is a nonapeptide, orally bioactive GnRH antagonist taken daily. One 24-week randomized trial showed similar efficacy between elagolix and DMPA for endometriosis-associated pain (Carr, 2014). Two phase III clinical trials assessed the clinical efficacy of a low-dose (150 mg daily) and a high-dose (200 mg twice daily) regimen provided for 6 months. Both regimens significantly reduced dysmenorrhea and nonmenstrual pelvic pain compared with placebo after 3 months. Compared with placebo, the high-dose regimen also led to lower levels of dyspareunia (Taylor, 2017). An extension of the above trials showed sustained improvements in dysmenorrhea, nonmenstrual pelvic pain, and dyspareunia at the 12-month mark. Greater effects were seen with the high-dose regimen (Surrey, 2018). Marketed in the United States as Orilissa, this agent appears best suited as second-line therapy after COCs.

Aromatase Inhibitors

In endometriotic tissue, estrogen may be produced locally through aromatization of circulating androgens. This may clarify the pathogenesis of postmenopausal endometriosis or may explain cases in which symptoms persist despite conventional treatment. Hormonal strategies described in prior sections target ovarian estrogen production but have little effect on estrogens produced from other sources. In contrast, aromatase inhibitors (AIs) block aromatase action and estradiol production in both the ovary and extraovarian sites. As a result, estrogen levels are dramatically suppressed, and AIs have hypoestrogenic side-effect profiles similar to those of GnRH agonists (Pavone, 2012). AIs used clinically include anastrozole (Arimidex) and letrozole (Femara).

A serious concern is ovarian cyst formation. Shown in Figure 21-3 (p. 456), by blocking the conversion of androgens to estrogens in ovarian granulosa cells, AIs reduce the negative feedback at the pituitary–hypothalamus level. This leads to increased GnRH secretion. Concomitant elevations in luteinizing hormone (LH) and follicle-stimulating hormone promote increased ovarian follicular development. Therefore, AIs always are combined with a progestins, COCs, or GnRH agonist to help blunt this significant side effect (Shippen, 2004).

Small studies that combined AIs with NETA or with COCs support this approach for pain relief (Amsterdam, 2005; Ferrero, 2009). However, due to side effects and limited data, such AI combinations are usually prescribed to women after other options for medical or surgical treatment have been exhausted (Dunselman, 2014).

Progesterone-Receptor Modulators

Progestins produce agonist effects upon binding to progesterone receptors. In contrast, progesterone antagonists and selective progesterone-receptor modulators (SPRMs) are agents that vary in their progesterone-receptor binding. Progesterone antagonists universally bind to and inactivate these receptors. SPRMS, depending on their individual pharmacologic profile, may activate or inactive progesterone receptors variably within different tissue types (Chap. 16, p. 366).

Of progesterone antagonists, mifepristone (Mifeprex) is currently FDA-approved solely for early pregnancy termination. When studied in patients with endometriosis, mifepristone reduced both pelvic pain and the extent of endometriosis (Kettel, 1996). Unfortunately, mifepristone's antiprogestational effects expose the endometrium to chronic unopposed estrogen. The resulting endometrial changes range from endometrial hyperplasia to a new category described as progesterone-receptor-modulator–associated endometrial changes (PAECs), described next (Mutter, 2008).

Of SPRMs, ulipristal acetate is available in the United States for emergency contraception as single-dose Ella. In Europe and Canada for presurgical treatment of leiomyomas, Esmya and Fibristal, respectively, are administered over several weeks. With long-term use, ulipristal acetate also is associated with endometrial PAECs, which carry unclear clinical significance for both eutopic and ectopic endometria. This limits its chronic use at this time. However, a recent systematic review of 10 studies and 1450 participants showed that ulipristal acetate–associated premalignant changes were rare (0.4 percent) and always reversible. PAEC developed in 40 to 80 percent of the participants that were treated with extended-use ulipristal acetate (De Milliano, 2017). Rare but serious liver injury also has been reported and is detailed in Chapter 9 (p. 208). Other SPRMs are still experimental at this time.

Selective Estrogen-Receptor Modulators

Bazedoxifene (BZA) is a third-generation selective estrogen-receptor modulator (SERM). Discussed in Chapter 22 (p. 482),

BZA is pharmacologically coupled with conjugated equine estrogen, and BZA/CEE (Duavee) is indicated for menopause symptom relief and osteoporosis prevention. BZA alone prompts lesion regression in an endometriosis rodent model (Lyu, 2015). Either alone or with a GnRH antagonist, BZA/CEE also was effective in a small case series for symptom suppression in patients with confirmed endometriosis (Hill, 2018).

Raloxifene is another SERM. Despite reassuring animal data showing implant regression, a subsequent trial using raloxifene in patients with endometriosis was stopped early due to early CPP relapse (Stratton, 2008; Yao, 2005).

Androgens

These agents are now used as second-line treatment for endometriosis due to their androgenic side effects. Danazol (Danocrine) is a synthetic 17α-ethinyl testosterone derivative. Its predominant action suppresses the midcycle LH surge to promote chronic anovulation (Floyd, 1980). It also occupies receptor sites on sex hormone–binding globulin to raise serum free testosterone levels and binds directly to androgen and progesterone receptors. In sum, danazol creates a hypoestrogenic, hyperandrogenic state that promotes endometriotic lesion atrophy (Godin, 2015).

Regarding efficacy, danazol given orally at dosages of 200 mg three times daily is superior to placebo to diminish endometriotic implant size and pelvic pain symptoms after 6 months of therapy (Telimaa, 1987). A metaanalysis of five clinical trials assessed danazol efficacy for endometriosis-associated symptoms, excluding infertility. Compared with placebo, danazol offered substantial pain relief (Selak, 2007).

The recommended dosage of danazol is 600 to 800 mg orally daily. Unfortunately, significant androgenic side effects develop and include acne, hot flashes, hirsutism, adverse serum lipid profiles, voice deepening (possibly irreversible), elevation of liver enzyme levels, and mood changes. Moreover, due to possible teratogenicity, this medication should be taken in conjunction with effective contraception. Because of its adverse side-effect profile, danazol is prescribed less frequently, and if administered, its duration is limited.

Gestrinone is an antiprogestational agent prescribed in Europe for endometriosis. It has antiprogestational, antiestrogenic, and androgenic effects. Gestrinone equals the effectiveness of danazol and of GnRH agonists for relief of endometriosis-related pain (Prentice, 2000). Furthermore, during 6 months of treatment, gestrinone was not associated with the BMD decline commonly seen with GnRH agonist use and was more effective in persistently decreasing moderate to severe pelvic pain (Gestrinone Italian Study Group, 1996). Unfortunately, one of the side effects of gestrinone appears to be lowering high-density lipoprotein (HDL) levels. Gestrinone can be administered as 2.5-mg oral twice weekly dose.

Surgical Treatment of Pain

Lesion Removal and Adhesiolysis

Because laparoscopy is the primary method for endometriosis diagnosis, concurrent surgical treatment is an attractive option. As evidence, diagnostic laparoscopy alone was compared with laparoscopic endometriotic lesion ablation plus uterine nerve ablation in one randomized trial. In the ablation group, 63 percent of women attained significant symptom relief compared with 23 percent in the expectant management group (Jones, 2001).

The optimal method to address endometriotic implants for maximal symptom relief is controversial. First, laser ablation does not appear to be more effective than conventional electrosurgical coagulation of endometriosis (Blackwell, 1991). Second, ablation and excision both appear to perform suitably. In one randomized trial, ablation was compared with excision of lesions in women with stage I or II endometriosis. At 6 months, similar reductions in pain scores were found (Wright, 2005). Another study showed no significant difference between ablation and excision at 12 months (Healey, 2010). However, at 5 years, the need for further hormonal or analgesic treatment was greater in the ablation group (Healey, 2014). For deeply infiltrative endometriosis, some authors have advocated radical surgical excision, although well-designed trials are lacking (Chapron, 2004).

Unfortunately, recurrence is common following surgical excision. Jones and associates (2001) demonstrated pain recurrence in 74 percent of patients at a mean time of 73 months postoperatively. The median time for recurrence was 20 months. After surgery for pain-related endometriosis, postoperative medical treatment may be elected to extend pain relief or treat residual pain. For this, the most rigorous evidence supports COCs or the LNG-IUS (Somigliana, 2014).

Adhesiolysis is postulated to effectively treat pain symptoms in women with endometriosis by restoring normal anatomy. However, most studies are poorly designed and retrospective. As a result, a definitive link between adhesions and pelvic pain is unclear (Hammoud, 2004). For example, one randomized trial demonstrated no overall pain relief from adhesiolysis compared with expectant management (Peters, 1992). However, within this study, one woman with severe, dense, vascularized bowel adhesions experienced pain relief following adhesiolysis.

Adhesion prevention during endometriosis surgery emphasizes sound surgical techniques described in Chapter 40 (p. 855). Of adhesion-prevention agents available in the United States, small studies show lower adhesions reformation rates with use of the cellulose barrier Interceed in endometriosis cases (Mais, 1995a; Sekiba, 1992). However, as noted by the American Society for Reproductive Medicine (2013), although peritoneal instillates and barriers may reduce postoperative adhesions, this has not translated clinically into improved pain, fertility, or bowel obstruction rates.

Endometrioma Resection

Endometriomas typically are treated surgically to exclude malignancy. To determine the best technique, both total ovarian cystectomy and aspiration coupled with cyst wall ablation have been compared. Of the two, cystectomy lowers endometrioma recurrence rates and pain symptoms and improves subsequent spontaneous pregnancy rates (Dan, 2013; Hart, 2008).

During surgery, steps are taken to preserve as much normal ovarian tissue as possible. To achieve this goal, electrosurgical coagulation of bleeding sites should be limited. As alternatives,

some have described use of dilute vasopressin or ovarian suturing (Pergialiotis, 2015; Qiong-Zhen, 2014). Other technical steps are described in Chapters 43 (p. 939) and 44 (p. 1030). Despite cystectomy, endometriomas may recur. Liu and coworkers (2007) found an approximately 15 percent recurrence rate at 2 years following initial surgery.

Importantly, women who undergo endometrioma excision may subsequently have reduced *ovarian reserve*, that is, the capacity to provide ova capable of fertilization (Somigliana, 2012). Additionally, surgery also raises the risk for adhesion formation. Both effects may diminish future fertility. Accordingly, in a woman who is asymptomatic, has a small endometrioma that displays classic findings, has a known endometriosis diagnosis, and has normal or stable CA125 levels, surveillance is an option (American College of Obstetricians and Gynecologists, 2016, 2018). This approach may benefit asymptomatic women with recurrent endometriomas, as repeat surgery can again diminish reserve (Ferrero, 2015). Following initial diagnosis, repeat TVS is recommended 6 to 12 weeks later to exclude a hemorrhagic cyst. Endometriomas then may be sonographically surveilled in asymptomatic women yearly or sooner, at the clinician's discretion (Levine, 2010). The main disadvantage to observation is an inability to exclude ovarian malignancy, and thus patient counseling is essential.

Presacral Neurectomy

For some women, transection of the presacral nerves lying within the presacral space may provide relief of CPP (Fig. 38-23, p. 812). This surgery is most effective for midline pain.

For endometriosis, results from a randomized trial revealed significantly greater pain relief at 12 months postoperatively in women treated with presacral neurectomy (PSN) and endometriotic excision compared with that from endometriotic excision alone (86 percent versus 57 percent) (Zullo, 2003). However, all of these women had midline pain. One metaanalysis demonstrated a significant decline in CPP after PSN compared with more conservative procedures, but only in those with midline pain (Proctor, 2005). PSN may be performed laparoscopically, but it is technically challenging. Moreover, postoperative constipation and voiding dysfunction due to involved nerve disruption are common (Huber, 2015). For these reasons, PSN is used in a limited manner and not recommended routinely for endometriosis-related pain relief.

Laparoscopic uterosacral nerve ablation (LUNA) destroys nerve fibers that pass to the uterus through the uterosacral ligaments. No evidence supports LUNA for endometriosis-related pain (Vercellini, 2003a). In a randomized trial of 487 women with CPP and with or without minimal endometriosis, LUNA did not improve pain, dysmenorrhea, dyspareunia, or quality-of-life scores compared with laparoscopy without pelvic denervation (Daniels, 2009).

Abdominal versus Laparoscopic Approach

All of the surgical procedures listed above can be completed through open or laparoscopic approaches. First, for benign ovarian masses such as endometriomas, strong evidence supports laparoscopy (Mais, 1995b; Yuen, 1997). Laparoscopic treatment of endometrioma carries an associated 5-percent risk for conversion to laparotomy. However, because of its efficacy and low rates of postoperative morbidity, laparoscopy is a preferred route when feasible (Canis, 2003).

For excision of endometriotic implants, laparoscopy is associated with demonstrated effectiveness and low morbidity rates. Moreover, adhesiolysis is preferred via laparoscopy when safe, and laparoscopy leads to less de novo adhesion formation than laparotomy (Gutt, 2004). Although requiring advanced skills, laparoscopic PSN appears to be as effective as laparotomy (Nezhat, 1992; Redwine, 1991).

Hysterectomy

This procedure is the definitive and most effective therapy for women with endometriosis who do not wish to retain fertility. It is appropriate for women with intractable pain, adnexal masses, or multiple previous conservative therapies or surgeries (American College of Obstetricians and Gynecologists, 2018). Hysterectomy for patients with endometriosis suitably may be completed laparoscopically, abdominally, or vaginally. However, adhesions and distorted anatomy secondary to endometriosis often makes a vaginal approach difficult, especially if adnexectomy is planned. Consequently, procedure route depends on equipment availability, operator experience, and disease extent.

Oophorectomy. Prior to hysterectomy for endometriosis, oophorectomy may be discussed. A general discussion of risks and benefits is found in Chapter 43 (p. 957). Specific to endometriosis, the benefits of pain relief and reoperation risks are measured against complications of hypoestrogenism.

In one study, of those with hysterectomy and bilateral salpingo-oophorectomy (BSO), 10 percent had recurrent CPP and 4 percent required reoperation. Compared with these women, those choosing ovarian conservation had a sixfold greater risk of recurrent pain and an eightfold greater risk of requiring additional surgery (Namnoum, 1995). In a second study, among all those choosing hysterectomy, ovarian conservation doubled the reoperation rate compared with those undergoing BSO (Shakiba, 2008). Moreover, in a subanalysis of those older than 40, ovary conservation lead to a sevenfold greater reoperation rate than BSO. However, in those younger than 40, reoperation rates did not differ whether ovaries were retained or removed. American College of Obstetricians and Gynecologists (2018) notes that ovarian conservation can be considered in patients undergoing hysterectomy if ovaries appear normal.

In epidemiologic studies, women with prior endometriosis have slightly greater ovarian cancer rates and higher proportions of clear cell and endometrioid subtypes (Kim, 2014; Pearce, 2012; Somigliana, 2006). That said, the risk is still small, and consensus guidelines do not recommend management changes based on this cancer potential (Dunselman, 2014).

Postoperative Hormone Replacement. Women with surgical menopause usually are younger and would likely benefit from estrogen replacement. Options are discussed in Chapter 22 (p. 479). Although evidence is lacking, some sources suggest that treatment in these women ideally continues until the time of expected natural menopause.

Unopposed estrogen is appropriate for hypoestrogenic women without a uterus. However, endometriosis recurrence has been reported with this therapy in women with severe endometriosis first treated with hysterectomy and BSO (Taylor, 1999). These symptoms required repeat surgery and did not recur with subsequent treatment with combined estrogen and progestin regimens. Additionally, cases of endometrial carcinoma have been reported in women with endometriosis treated with unopposed estrogen after hysterectomy and BSO (Reimnitz, 1988; Soliman, 2006). This is rare and may arise from incompletely resected pelvic endometriosis. Therefore, adding a progestin to estrogen replacement therapy can be considered in women with severe endometriosis that was treated surgically (Moen, 2010). However, the risks of malignancy are balanced against the adverse lipid changes and breast cancer risks associated with adding progesterone to estrogen replacement therapy.

The optimal timing for estrogen replacement initiation following hysterectomy with BSO is guided by limited data. One small study showed no significant differences in postoperative recurrent pain rates whether hormones were begun immediately after surgery or were delayed (Hickman, 1998).

Endometriosis-Related Infertility

For an asymptomatic woman with infertility, laparoscopy solely to exclude endometriosis is unwarranted (American Society for Reproductive Medicine, 2012). For those with endometriosis-related pain undergoing medical therapy, treatment does not raise fecundity (Hughes, 2007). An exception is the use of GnRH agonists for endometriosis treatment in patients who plan to undergo IVF or intracytoplasmic sperm injection (ICSI). Namely, a Cochrane review assessed three randomized trial of GnRH agonist treatment in patients with endometriosis planning IVF. Treatment significantly raised pregnancy rates (Sallam, 2006).

For women with infertility and minimal to mild endometriosis, surgical ablation may be beneficial, although the effect appears small (Marcoux, 1997). However, other researchers report a fertility benefit from surgical ablation for mild to moderate endometriosis (Parazzini, 1999). A metaanalysis of these two studies did demonstrate an advantage for laparoscopic surgery compared with diagnostic laparoscopy alone. Based on this study, nearly eight women would need to under laparoscopic surgery for one additional clinical pregnancy (Jacobson, 2002, 2010).

Moderate to severe endometriosis may be treated with surgery to restore normal anatomy and tubal function. However, for women with severe endometriosis, well-designed trials examining the role of surgery for subfertility are limited (Crosignani, 1996). In infertile women with stage III/IV endometriosis, clinicians can consider operative laparoscopy, instead of expectant management, to increase spontaneous pregnancy rates (Dunselman, 2014). However, after initial unsuccessful surgery for infertility, IVF is preferable to reoperation (Pagidas, 1996).

Alternatively, patients with endometriosis and infertility are candidates for fertility treatments such as controlled ovarian hyperstimulation, intrauterine insemination, and IVF (Chap. 21, p. 450). In particular, IVF is the most effective treatment for infertility in patients with endometriosis. Numerous studies show similar live-birth rates following IVF in patients with all stages of endometriosis (endometriomas excluded) and patients without this disease (Bukulmez, 2001; Opøien, 2012; Ozkan, 2008).

PAIN PATHOPHYSIOLOGY

Pain in the lower abdomen and pelvis is a common complaint. Diagnosis can be challenging due to the wide differential diagnosis that spans multiple organ systems. Clinicians ideally should understand the mechanisms underlying human pain perception, which involves complex physical, biochemical, emotional, and social interactions.

Pain is a protective mechanism meant to warn of an immediate threat and to prompt withdrawal from noxious stimuli. Pain is usually followed by an emotional response and behavioral consequences. The mere threat of discomfort may elicit emotional responses even without actual injury.

When categorized, pain may be considered *somatic* or *visceral* depending on the type of afferent nerve fibers involved. Additionally, pain is described by the physiologic steps that produce it and can be defined as *inflammatory* or *neuropathic* (Kehlet, 2006). Both categories are helpful for diagnosis and treatment.

Somatic or Visceral Pain

Somatic pain stems from nerve afferents of the somatic nervous system, which innervates the parietal peritoneum, skin, muscles, and subcutaneous tissues. Somatic pain is typically sharp and localized. It is found on either the right or left within dermatomes that correspond to the innervation of involved tissues (Fig. 12-1).

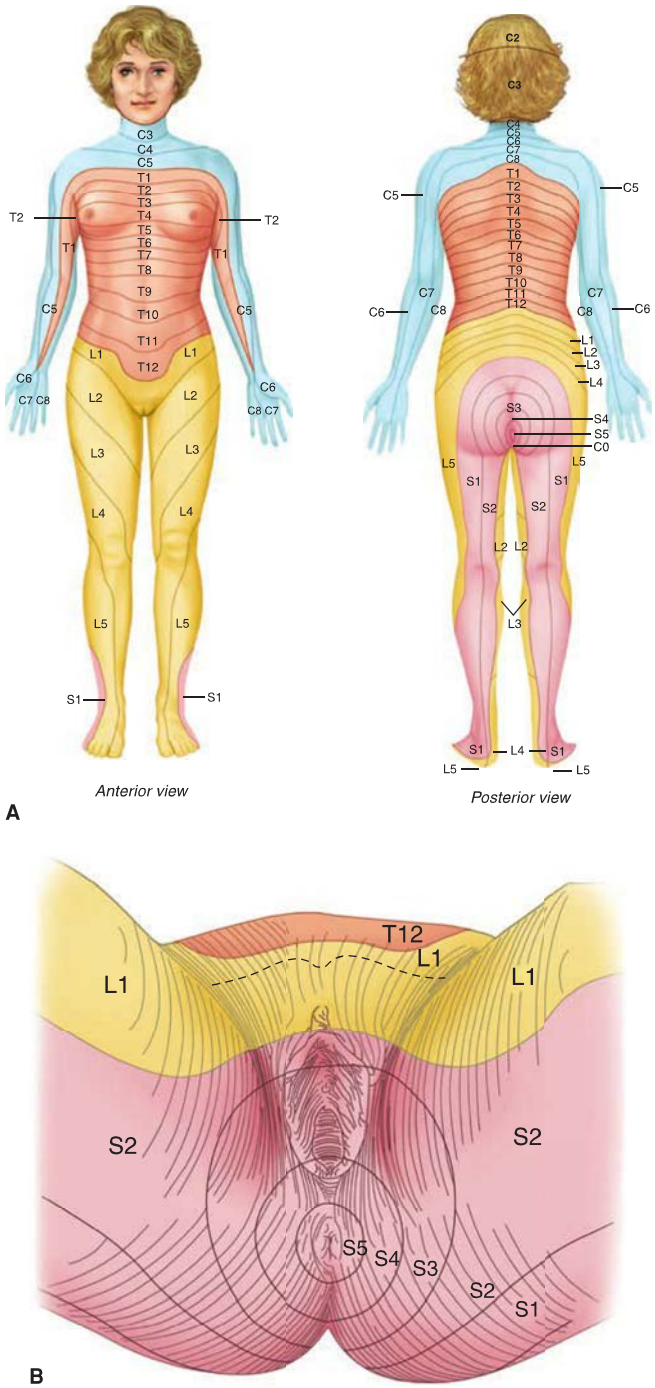

FIGURE 12-1 Dermatome maps. A dermatome is an area of skin supplied by a single spinal nerve. **A.** Body dermatomes. **B.** Perineal dermatomes.

In contrast, visceral pain stems from afferent fibers of the autonomic nervous system, which transmits information from the viscera and visceral peritoneum. Noxious stimuli typically include stretch, ischemia, or spasm of abdominal organs. The visceral afferent fibers that transfer these stimuli are sparse. Thus, the resulting diffuse sensory input leads to a generalized, dull ache.

Visceral pain often localizes to the midline because visceral innervation of abdominal organs is usually bilateral (Flasar, 2006). Also, visceral pain is typically localized by the brain's sensory cortex to an approximate spinal cord level that is determined by the embryologic origin of the involved organ. For example, pathology in midgut organs, such as the small bowel, appendix, and caecum, causes perceived periumbilical pain. In contrast, disease in hindgut organs, such as the colon and intraperitoneal portions of the genitourinary tract, causes midline suprapubic or hypogastric pain (Gallagher, 2004).

Visceral afferent fibers are poorly myelinated, and action potentials can easily spread from them to adjacent somatic nerves. As a result, visceral pain may at times be referred to dermatomes that correspond to these adjacent somatic nerve fibers (Giamberardino, 2003). In addition, both peripheral somatic and visceral nerves often synapse in the spinal cord at the same dorsal horn neurons. These neurons, in turn, relay sensory information to the brain. The cortex recognizes the signal as coming from the same dermatome regardless of its visceral or somatic nerve origin. This phenomenon is termed *viscerosomatic convergence* and makes it difficult for a patient to distinguish internal organ pain from abdominal wall or pelvic floor pain (Perry, 2003).

In contrast, *direct intraspinal neuronal reflexes* permit transmission of visceral nociceptive input to other pelvic viscera (viscerovisceral reflex), muscle (visceromuscular reflex), and skin (viscerocutaneous reflex). These intraspinal reflexes may explain why patients with endometriosis or interstitial cystitis/bladder pain syndrome (IC/BPS) manifest other pain syndromes such as vestibulitis, pelvic floor myalgia, or irritable bowel syndrome (IBS). Thus, unless the underlying chronic visceral pain source is identified and properly treated, referred pain and secondary pain syndromes may not be successfully eliminated (Perry, 2000).

Inflammatory Pain

With acute pain, noxious stimuli such as a knife cut, burn, or crush injury activate sensory pain receptors, more formally termed *nociceptors*. Action potentials travel from the periphery to dorsal horn neurons in the spinal cord. Here, reflex arcs may lead to immediate muscle contraction, which removes and protects the body from harm. Additionally, within the spinal cord, sensory information is augmented or dampened and may then be transmitted to the brain. In the cortex, it is recognized as pain (Janicki, 2003). After an acute stimulus is eliminated, nociceptor activity quickly diminishes.

If tissues are injured, inflammation usually follows. Chemical mediators of this process are prostaglandins, which are released from the damaged tissue, and cytokines, which are produced in white blood cells and endothelial cells. These sensitizing mediators lower the conduction threshold of nociceptors. This is termed *peripheral sensitization*. Similarly, neurons within the spinal cord and/or brain display enhanced excitability, termed *central sensitization.* As a result, within inflamed tissues, the perception of pain is increased relative to the strength of the external stimulus (Kehlet, 2006). Normally, as inflammation declines and healing ensues, the greater sensitivity to stimuli and thus the perception of pain subsides.

Neuropathic Pain

In some individuals, sustained noxious stimuli can lead to persistent central sensitization and permanent loss of neuronal inhibition. As a result, a lower threshold to painful stimuli remains despite resolution of the inciting stimuli (Butrick, 2003). This persistence characterizes *neuropathic pain*, which is felt to underlie many chronic pain syndromes. During central sensitization, neurons within spinal cord levels above or below those initially affected may eventually become involved, resulting in chronic pain that may be referred across several spinal cord levels. In addition, some evidence suggests that chronic pain states are also associated with regional brain morphology changes in regions known to regulate pain. This has been described as maladaptive central nervous system (CNS) plasticity (As-Sanie, 2012). The concept of neuropathic pain helps explain in part why many patients with chronic pain have discomfort disproportionately greater than the amount of coexistent disease.

Thus, in assessing patients with chronic pain, a clinician may find an ongoing inflammatory condition. In these cases, inflammatory pain dominates, and treatment is directed at resolving the underlying inflammatory condition. However, for many, evaluation may reveal no or minimal current pathology. In these cases, pain is neuropathic, and treatment thus focuses on management of pain symptoms themselves.

ACUTE PAIN

History

Acute pelvic pain is defined as pain in the lower abdomen or pelvis lasting <3 months. The range of causes is extensive, and a thorough history and physical examination can narrow the list (Table 12-1). Generally, potentially life-threatening or other urgent conditions are excluded first and include pregnancy complications, appendicitis, ovarian torsion, pelvic inflammatory disease (PID), and ruptured ovarian cyst or abscess.

During evaluation, a verbal description of the pain and its associated factors is essential. For example, duration can be informative, and pain with abrupt onset may be more often associated with organ torsion, rupture, or ischemia. Patients with acute pathology involving pelvic viscera may describe *visceral pain* that is midline, diffuse, dull, achy, or cramping. One example is the midline periumbilical pain of early appendicitis. Patients may repeatedly shift or roll to one side to find a comfortable position.

The underlying pelvic pathology may extend from the viscera to inflame the adjacent parietal peritoneum. In these cases, sharp *somatic pain* is described, which is localized, often unilateral,

TABLE 12-1. Etiologies of Acute Lower Abdominal and Pelvic Pain

Gynecologic	
PID	Dysmenorrhea
Tuboovarian abscess	Mittelschmerz
Ectopic pregnancy	Ovarian mass
Incomplete abortion	Ovarian torsion
Prolapsing leiomyoma	Obstructed outflow tract
Gastrointestinal	
Gastroenteritis	Inflammatory bowel disease
Colitis	Irritable bowel disease
Appendicitis	Obstructed small bowel
Diverticulitis	Mesenteric ischemia
Constipation	Malignancy
Urologic	
Cystitis	Urinary tract stone
Pyelonephritis	Perinephric abscess
Musculoskeletal	
Hernia	Abdominal wall trauma
Miscellaneous	
Peritonitis	Sickle cell crisis
Diabetic ketoacidosis	Vasculitis
Herpes zoster	Abdominal aortic aneurysm rupture
Opiate withdrawal	

PID = pelvic inflammatory disease.

and focused to a specific corresponding dermatome. Again using appendicitis as an example, the classic migration of pain to the site of peritoneal irritation in the right lower quadrant illustrates acute somatic pain. In other instances, sharp, localized pain may originate not from the parietal peritoneum, but from pathology in specific muscles or in isolated areas of skin or subcutaneous tissues. In these instances, with somatic pain, patients classically rest motionless to avoid movement of the affected peritoneum, muscle, or skin.

Colicky pain may reflect bowel obstructed by adhesion, neoplasia, stool, or hernia. It can also stem from greater bowel peristalsis in those with IBS, inflammatory bowel disease, or infectious gastroenteritis. Alternatively, colic may follow forceful uterine contractions with the passage of products of conception, pedunculated leiomyomas, or endometrial polyps. Last, stones in the lower urinary tract may cause spasms of pain as they are passed.

Associated symptoms may also direct diagnosis. For example, absence of dysuria, hematuria, frequency, or urgency will exclude urinary pathology in most instances. Gynecologic causes are often associated with vaginal bleeding, vaginal discharge, dyspareunia, or amenorrhea. Alternatively, exclusion of diarrhea, constipation, or gastrointestinal (GI) bleeding lowers the probability of GI disease.

Vomiting complaints, however, are less informative, although the temporal relationship of vomiting to the pain may be helpful. In the acute surgical abdomen, if vomiting occurs, it usually follows as a response to pain and results from vagal stimulation. This vomiting is typically severe and develops without nausea. For example, vomiting has been found in approximately 75 percent of adnexal torsion cases (Descargues, 2001; Huchon, 2010). Conversely, if vomiting is noted prior to pain onset, a surgical abdomen is less likely (Miller, 2006).

Physical Examination

Examination begins with patient observation during initial questioning. Her general appearance, including facial expression, diaphoresis, pallor, and degree of agitation, often indicates the urgency of the clinical condition.

Elevated temperature, tachycardia, and hypotension will prompt an expedited evaluation, as the risk for intraabdominal pathology rises with their presence. Constant, low-grade fever is common in inflammatory conditions such as diverticulitis and appendicitis, and higher temperatures may be seen with PID, advanced peritonitis, or pyelonephritis.

Pulse and blood pressure evaluations ideally assess orthostatic changes if intravascular hypovolemia is suspected. A pulse rise of 30 beats per minute or a systolic blood pressure drop of 20 mm Hg or both, between lying and standing after 1 minute, is often reflective of hypovolemia. If noted, establishment of intravenous (IV) access and fluid resuscitation may be required prior to examination completion. Notably, certain neurologic disorders and medications, such as tricyclic antidepressants or antihypertensives, may produce similar orthostatic blood pressure changes.

Abdominal examination is essential. Visual inspection of the abdomen focuses on prior surgical scars, which raise the possibility of bowel obstruction from adhesions or incisional hernia. Additionally, abdominal distention may reflect bowel obstruction, perforation, ascites, or secondary intestinal dysmotility. After inspection, auscultation can identify hyperactive or high-pitched bowel sounds characteristic of bowel obstruction. Hypoactive sounds, however, are less informative.

Palpation of the abdomen systematically explores each quadrant and begins away from the area of indicated pain. Peritoneal irritation is suggested by rebound tenderness or by abdominal rigidity due to involuntary guarding or reflex spasm of the adjacent or involved abdominal muscles. A positive Carnett sign was found in one study to be 95-percent accurate at distinguishing between pain originating from abdominal wall pathology or from visceral sources (Thomson, 1977). Carnett sign is pain with elevation of the head and shoulders, and this lifting concurrently tenses the abdominal wall muscles. It is typical of anterior abdominal wall pathology.

Pelvic examination in general is performed in reproductive-aged women, as gynecologic pathology and pregnancy complications are a common pain source in this age group. The decision to pursue pelvic examination in geriatric and pediatric patients is based on clinical information.

Of findings, purulent vaginal discharge or cervicitis often accompanies reproductive tract infection. Vaginal bleeding can stem from pregnancy complications, reproductive tract neoplasia, or acute vaginal trauma. Leiomyomas, pregnancy, hematometra, and adenomyosis are frequent causes of uterine enlargement, and the last three may also create uterine softening. Cervical motion tenderness reflects peritoneal irritation from pus or blood. A tender adnexal or pelvic mass may reflect ectopic pregnancy;

tuboovarian abscess; ovarian cyst with torsion, hemorrhage, or rupture; or nongynecologic pathology of the appendix or colon.

Rectal examination can add information regarding the source and size of pelvic masses and the possibility of colorectal disease. Stool guaiac testing for occult blood may add information in patients with rectal bleeding, painful defecation, or significant changes in bowel habits.

In emergency departments, women with acute pain may experience waits between their initial assessment and subsequent testing. For these patients, literature supports early administration of analgesia. Fears that analgesia will mask patient symptoms and hinder accurate diagnosis have not been supported (Manterola, 2011). Thus, barring significant hypotension or drug allergy, analgesia may be administered judiciously in these situations. In general, well-localized pain or tenderness, persisting longer than 6 hours and unrelieved by analgesics, has a greater likelihood of acute peritoneal pathology.

Laboratory Testing

Despite benefits from a thorough history and physical examination, the sensitivity of these two in diagnosing abdominal pain is low (Gerhardt, 2005). Thus, laboratory and diagnostic testing are typically required. First, either urine or serum β-human chorionic gonadotropin testing is recommended in those of reproductive age without prior hysterectomy. Complete blood count can identify hemorrhage, both uterine and intraabdominal, and can assess for infection. Urinalysis helps evaluate possible urolithiasis or cystitis. Microscopic evaluation and culture of vaginal discharge may add support to suspected cases of reproductive tract infection. Last, specific measures of GI dysfunction can be selected as indicated.

Radiologic Imaging

If an obstetric or gynecologic cause is suspected, transvaginal and transabdominal pelvic sonography are preferred modalities (Bhosale, 2016). Sonography is widely available, can usually be obtained quickly, requires little patient preparation, is relatively noninvasive, and avoids ionizing radiation. In most cases, transvaginal sonography (TVS) offers superior resolution of the reproductive organs (Chap. 2, p. 29). Transabdominal sonography may still be necessary if the uterus or adnexal structures are significantly large or lie beyond the transvaginal probe's field of view. In women with acute pain, the addition of Doppler studies is particularly useful if adnexal torsion or ectopic pregnancy is suspected (Twickler, 2010). Less common causes of acute pain amenable to sonographic diagnosis are perforation of the uterine wall by an intrauterine device or menstrual outflow obstruction from müllerian agenesis anomalies. For these, 3-dimensional (3-D) TVS has become invaluable (Bermejo, 2010; Moschos, 2011). Instead, computed tomography (CT) offers a more global examination that can identify numerous abdominal and pelvic conditions, often with a high level of confidence (Hsu, 2005). CT performs the best for identifying structural urinary tract and GI causes of acute pelvic pain (Bhosale, 2016).

The debate regarding CT safety and possible overuse is ongoing (Brenner, 2007). Of major concern is the potential higher cancer risk directly attributable to ionizing radiation (Einstein, 2007). Investigators in a large multicenter analysis found the median effective radiation dose from a multiphase abdominopelvic CT scan was 31 mSv, and this correlates with a lifetime attributed risk of four cancers per 1000 patients (Smith-Bindman, 2009). However, in an acute setting, CT imaging benefits frequently outweigh this risk.

In some instances, plain film radiography is selected. Although its sensitivity is low for most gynecologic conditions, it still may be informative if bowel obstruction or perforation is suspected (Leschka, 2007). Dilated loops of small bowel, air-fluid levels, free air under the diaphragm, or the presence or absence of colonic gas are significant findings.

Magnetic resonance (MR) imaging may play a role if initial sonography is nondiagnostic. Common reasons include patient obesity and pelvic anatomy distortion secondary to large leiomyomas, müllerian anomalies, or exophytic tumor growth. As a first-line tool, MR imaging is often selected for pregnant patients, in whom ionizing radiation exposure is ideally limited. However, for most acute disorders, it provides little advantage over 3-D sonography or CT (Bermejo, 2010; Brown, 2005). Limited availability can be another disadvantage.

Laparoscopy

Operative laparoscopy is the primary treatment for suspected appendicitis, adnexal torsion, ruptured ectopic pregnancy, and ruptured ovarian cyst associated with ongoing hemorrhage. However, diagnostic laparoscopy may be indicated in patients with severe pain if no pathology can be identified after a conventional evaluation is completed (Sauerland, 2006).

The decision to perform a surgical procedure for acute pelvic pain can be challenging. In a patient with signs of peritoneal irritation, possible hemoperitoneum, shock, and/or impending sepsis, the decision to operate is made decisively unless contraindications to immediate surgery are present. Although patients with torsion are often stable, this condition is a surgical emergency due to the time urgency in relieving ischemia to preserve fertility and ovarian function (Sauerland 2006). Surgical intervention may also be expedited for conditions that are causing severe uncontrolled pain or are refractory to supportive or medical management.

CHRONIC PAIN

Persistent pain may be visceral, somatic, or mixed in origin. As a result, it may take several forms in women, and these include chronic pelvic pain (CPP), dysmenorrhea, dyspareunia, dysuria, musculoskeletal pain, intestinal cramping, or vulvodynia. Vulvodynia is discussed in Chapter 4 (p. 104). The list of possible underlying pathologies is extensive (Table 12-2). Moreover, pathology in one organ can commonly lead to dysfunction in adjacent systems and create overlapping symptoms (Maixner, 2016). A comprehensive evaluation of multiple organ systems and psychologic state is essential for complete treatment.

CHRONIC PELVIC PAIN

This common gynecologic problem has an estimated prevalence of 15 percent in reproductive-aged women (Mathias, 1996).

TABLE 12-2. Diseases That May Be Associated with Chronic Pelvic Pain in Women

Gynecologic		
Endometriosis	Reproductive tract cancer	Chronic PID
Adenomyosis	Pelvic muscle trigger points	Chronic endometritis
Leiomyomas	Intrauterine contraceptive device	Vestibulitis
Abdominal adhesions	Outflow tract obstruction	Pelvic congestion syndrome
Endometrial/endocervical polyps	Ovarian retention syndrome	Broad ligament herniation
Ovarian mass	Ovarian remnant syndrome	Chronic ectopic pregnancy
Adnexal cysts		Postoperative peritoneal cysts
Pelvic organ prolapse		
Urologic		
Chronic UTI	Urethral syndrome	Interstitial cystitis
Detrusor dyssynergia	Urethral diverticulum	Radiation cystitis
Urinary tract stone	Urinary tract cancer	
Gastrointestinal		
Irritable bowel syndrome	Colitis	Celiac disease
Constipation	Inflammatory bowel disease	Chronic intermittent bowel obstruction
Diverticular disease	Gastrointestinal cancer	
Musculoskeletal		
Hernias	Myofascial pain	Vertebral compression
Muscular strain	Levator ani syndrome	Disc disease
Faulty posture	Fibromyositis	Coccydynia
Degenerative joint disease	Spondylosis	Peripartum pelvic pain
Neurologic		
Neurologic dysfunction	Neuralgia of iliohypogastric, ilioinguinal, lateral femoral cutaneous, or genitofemoral nerves	Spinal cord or sacral nerve tumor
Pudendal neuralgia		
Piriformis syndrome	Abdominal cutaneous nerve entrapment	
Miscellaneous		
Psychiatric disorders		
Physical or sexual abuse		
Shingles		

PID = pelvic inflammatory disease; UTI = urinary tract infection.

No definition is universally accepted. However, most include pain that: (1) is present for >6 months; (2) localizes to the pelvis, lower abdomen, lower back, medial thigh, or perineum; (3) has various pain manifestations; and (4) presents variably in duration and cyclicity (Doggweiler, 2017).

Causes of CPP are broad. Of gynecologic causes, endometriosis is the most prevalent and found in 70 to 90 percent of patients with pelvic pain (American Society for Reproductive Medicine, 2014). Dysmenorrhea is the most frequent endometriosis symptom, but intermittent or continuous nonmenstrual pain also may be present. Endometriosis is fully described in Chapter 11. Other etiologies are discussed subsequently.

History

A detailed history is integral to CPP diagnosis, and a pelvic pain questionnaire can be used initially. One example is available from the International Pelvic Pain Society at: https://www.pelvicpain.org/. Additionally, a body silhouette diagram can be provided to patients for them to mark specific sites of pain. The McGill Pain Questionnaire and Short Form combines a list of pain descriptors with a body map for patients to mark pain sites (Melzack, 1987). Pain scales also can quantify discomfort and include visual analogue scales (VAS) and verbal descriptor scales (VDS) (Fig. 12-2). At minimum, the series of questions found in Table 12-3 can provide valuable information.

First, of gynecologic factors, pregnancy and delivery can be traumatic to neuromuscular structures and is associated with pelvic organ prolapse, pelvic floor muscle myofascial pain syndromes, and symphyseal or sacroiliac joint pain. In addition, injury to the ilioinguinal or iliohypogastric nerves during Pfannenstiel incision for cesarean delivery may lead to lower abdominal wall pain even years after the initial injury (Whiteside, 2003). Following delivery, recurrent, cyclic pain and swelling in

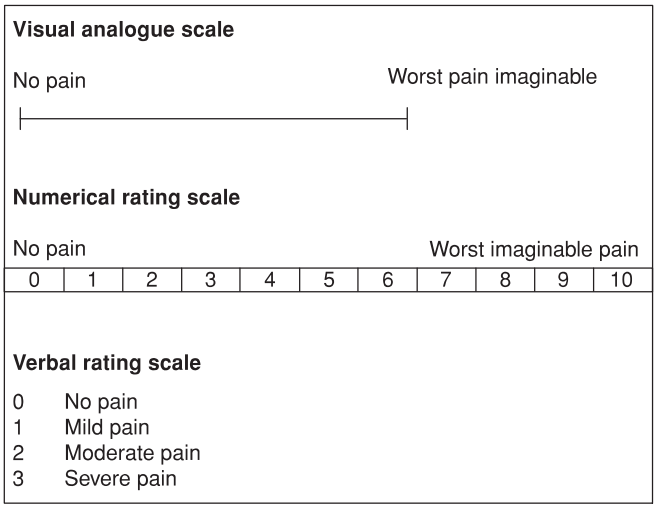

FIGURE 12-2 Rating scales for pain. The visual analogue, numeric, and verbal rating scales are shown.

the vicinity of a cesarean incision or within an episiotomy suggests endometriosis within the scar itself (Fig. 11-3, p. 238). In a nullipara with infertility, pain may stem more often from endometriosis, pelvic adhesions, or PID.

TABLE 12-3. Questions Relevant to Chronic Pelvic Pain

1. Describe the location, quality, severity, and timing of your pain.
2. When and how did your pain start and how has it changed?
3. What makes your pain better or worse?
4. What other symptoms or health problems do you have?
5. Do you have frequency, urgency, or bloody urine?
6. Do you have nausea or vomiting, diarrhea, constipation, or rectal bleeding?
7. Do you have pain with your periods?
8. Did your pain start initially as menstrual cramps?
9. Have you had surgery? What was the reason?
10. How many pregnancies have you had?
11. How did you deliver? Was there an episiotomy?
12. What form of birth control do you use and have you used in the past?
13. Have you ever been treated for a sexually transmitted disease or pelvic infection?
14. Do you have pain with deep penetration during intercourse?
15. Are you depressed or anxious?
16. Have you been treated for mental illness in the past?
17. Have you been or are you now being abused physically or sexually?
18. What prior evaluations or treatments have you had for your pain?
19. Have any of the previous treatments helped?
20. What medications are you taking now?
21. How has the pain affected your quality of life?
22. What do you believe or fear is causing your pain?

Second, prior abdominal surgery raises the risk for pelvic adhesions, especially if infection, bleeding, or large areas of denuded peritoneal surfaces were involved. Adhesions were found in 40 percent of patients who underwent laparoscopy for CPP suspected to be of gynecologic origin (Sharma, 2011). The incidence of adhesions increases with the number of prior surgeries (Dubuisson, 2010). Last, certain disorders persist or commonly recur, and thus information regarding prior surgeries for endometriosis, adhesive disease, or malignancy is sought.

Of psychologic risk factors, CPP and sexual abuse are significantly associated (Jamieson, 1997; Lampe, 2000). A metaanalysis found sexual abuse linked with a higher lifetime diagnosis rate of functional bowel disorders, fibromyalgia, psychogenic seizure disorder, and CPP (Paras, 2009). Additionally, for some women, CPP is an acceptable means to cope with social stresses. Thus, patients are questioned regarding intimate partner violence and satisfaction with family relationships. Furthermore, depression may cause or result from CPP, and Table 14-3 (p. 303) provides one assessment tool. Other conditions bearing similarities to CPP include fibromyalgia, chronic fatigue syndrome, temporomandibular disorder, and migraine. These are referred to as functional somatic syndromes, and CPP may be comorbid with each of these (Warren, 2011).

Physical Examination

In a woman with chronic pain, even routine examination may be extremely painful. Thus, examination proceeds slowly to allow relaxation between each step. Moreover, a patient is reassured that she may ask for the examination to stop at any time. Terms used to describe examination findings include *allodynia* and *hyperesthesia*, among others. Allodynia is a painful response to a normally innocuous stimulus, such as a cotton swab. Hyperalgesia is an extreme response to a painful stimulus.

Stance and Gait

Women with intraperitoneal pathology may compensate with changes in posture. Such adjustments can create secondary musculoskeletal sources of pain (p. 270). Alternatively, musculoskeletal structures may be the site of referred pain from these organs (Table 12-4). Initial studies estimated that 14 to 22 percent of women with CPP have pain arising primarily or secondarily from musculoskeletal sources (Reiter, 1991; Tu, 2006). In specialty clinics, in which a standard musculoskeletal examination is incorporated, the reported musculoskeletal dysfunction prevalence rises to 50 to 90 percent (Fitzgerald, 2011; Lamvu, 2015; Mieritz, 2016; Sedighimehr, 2018).

Initially, a woman is examined while standing. Posture is evaluated anteriorly, posteriorly, and laterally. Anteriorly, the umbilicus, symmetry of the anterior superior iliac spines (ASISs), and weight bearing is evaluated. If one leg bears most of the weight, the nonbearing leg is often externally rotated and slightly flexed at the knee. Next, the anterior abdominal wall and inguinal areas are inspected for hernias (p. 270). Inspection of the perineum and vulva with the patient standing may identify varicosities. These are often asymptomatic or may cause superficial discomfort. Such varicosities may coexist with internal pelvic varicosities, the underlying cause of pelvic congestion syndrome (p. 264).

TABLE 12-4. Musculoskeletal Origins of Chronic Pelvic Pain

Structure	Innervation	Referred Pain Site(s)
Hip	T12–S1	Lower abdomen; anterior medial thigh; knee
Lumbar ligaments, facets/disks	T12–S1	Low back; posterior thigh and calf; lower abdomen; lateral trunk; buttock
Sacroiliac joints	L4–S3	Posterior thigh; buttock; pelvic floor
Abdominal muscles	T5–L1	Abdomen; anteromedial thigh; sternum
Pelvic and back muscles		
Iliopsoas	L1–L4	Lateral trunk; lower abdomen; low back; anterior thigh
Piriformis	L5–S3	Low back, buttock; pelvic floor
Pubococcygeus	S1–L4	Pelvic floor; vagina; rectum; buttock
Obturator internal/external	L3–S2	Pelvic floor; buttock; anterior thigh
Quadratus lumborum	T12–L3	Anterior lateral trunk; anterior thigh; lower abdomen

Posteriorly, inspection for scoliosis and of horizontal stability of the shoulders, gluteal folds, and knee creases is completed. Asymmetry may reflect musculoskeletal disorders.

Lateral visual examination searches for lordosis and concomitant kyphosis. This combination has been noted in some women with CPP and termed *typical pelvic pain posture (TPPP)* (Fig. 12-3) (Baker, 1993). Also, abnormal tilt of the pelvic bones can be assessed by simultaneously placing an open palm on each side between the posterior superior iliac spine (PSIS) and the ASIS. Normally, the ASIS lies one quarter inch below the level of the PSIS, and greater distances may suggest abnormal tilt. Pelvic tilt may be associated with hip osteoarthritis and other orthopedic problems (Labelle, 2005; Yoshimoto, 2005).

To augment passive inspection, a woman is asked to perform a Valsalva maneuver. Diastasis of the rectus abdominis muscle or hernias may become evident. With diastasis, the borders of the rectus abdominis muscle can be palpated bilaterally along the entire length of the protrusion.

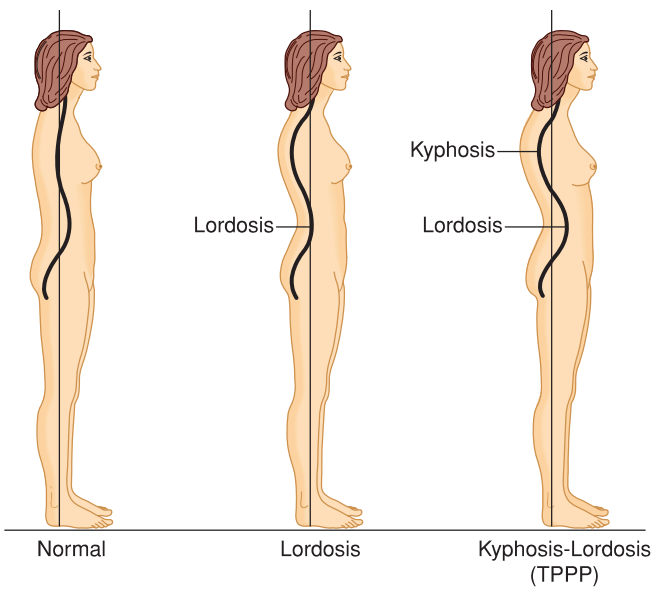

FIGURE 12-3 Concurrent lordosis and kyphosis are common postural changes associated with chronic pelvic pain. TPPP = typical pelvic pain posture.

Mobility limitations also can be informative. Thus, a patient is asked to bend forward at the waist. Limitation in forward flexion may reflect primary orthopedic disease or adaptive shortening of back extensor muscles. This shortening is seen frequently in women with chronic pain and TPPP. In such cases, patients are unable to bend over at the waist to create the normal convex curve. Gait is evaluated by having the patient walk across the room. An antalgic gait, known as a limp, indicates a higher probability of musculoskeletal pain.

Muscle weakness may also indicate orthopedic disease. A Trendelenburg test, in which a patient is asked to balance on one foot, can indicate dysfunction of hip abductor muscles or hip joint. With a positive test, when a woman elevates a leg by flexing the hip, the ipsilateral iliac crest droops.

Sitting and Supine

A patient is next invited to sit on the examining table. Myofascial pain syndrome may involve pelvic floor muscles and often leads to a patient shifting weight to one buttock or sitting toward a chair's front edge.

Next, with the patient supine, the anterior abdominal wall is evaluated for abdominal scars. These may be sites of hernia or nerve entrapment or may indicate a risk for intraabdominal adhesive disease. Auscultation for bowel sounds and bruits follows. Increased bowel activity may reflect IBS or inflammatory bowel disease. Bruits prompt investigation for vascular pathology.

While supine, a woman is asked to demonstrate with one finger the point of maximal pain and then encircle the total surrounding area of involvement. Superficial palpation of the anterior abdominal wall by a clinician may reveal sites of tenderness or knotted muscle that may reflect nerve entrapment or myofascial pain syndrome (p. 270). Carnett sign, described on page 255, is typical of anterior abdominal wall pathology. Conversely, with pain originating from inside the abdominal cavity, discomfort usually decreases during this maneuver (Thomson, 1991). Last, deep palpation of the lower abdomen may identify pathology originating from pelvic viscera. Dullness to percussion or a shifting fluid wave can reflect ascites. Lower extremity mobility also is evaluated. In most cases, a woman can elevate her leg 80 degrees from the horizontal toward her head, termed a *straight leg test*. Pain with leg elevation may be seen with lumbar disc, hip joint, or myofascial pain syndromes.

Additionally, symphyseal pain with this test may indicate laxity in the symphysis pubis or pelvic girdle. Both the obturator and iliopsoas tests may indicate myofascial pain syndromes involving these muscles or disorders of the hip joint. With the obturator test, a supine patient brings one knee into 90 degrees of flexion while the same foot remains planted. The ankle is held stationary, but the knee is gently pulled laterally and then medially to assess for tenderness. With the iliopsoas test, a supine woman attempts to flex each hip separately against downward resistance from the examiner's hand placed on the ipsilateral anterior thigh. If pain is described with hip flexion, the test result is positive.

Pelvic Examination

Pelvic examination begins with inspection of the vulva for generalized changes and localized lesions. Vulvar erythema often reflects infectious vulvitis, described in Chapter 3 (p. 57), or vulvitis stemming from dermatoses (Chap. 4, p. 94). The vestibular area also is examined. Erythema of the vestibule, with or without punctate lesions, may indicate vestibulitis. Following this inspection, systematic pressure point palpation of the vestibule, shown in Figure 4-1 (p. 93), is completed using a small cotton swab to assess for pain. Last, the anocutaneous reflex, described in Chapter 24 (p. 544), may be performed to assess pudendal nerve integrity.

Prior to speculum examination, a single digit systematically evaluates the vagina. Pain elicited from pressure beneath the urethra may indicate urethral diverticulum. Pain with anterior vagina palpation under the trigone can reflect IC/BPS. Systematic sweeping pressure against the pelvic floor muscles along their length may identify isolated taut muscle knots from pelvic floor myofascial syndrome. Of these muscles, the pubococcygeus, iliococcygeus, and obturator internus muscles can usually be reached with a vaginal finger (Fig. 12-4). Next, insertion points

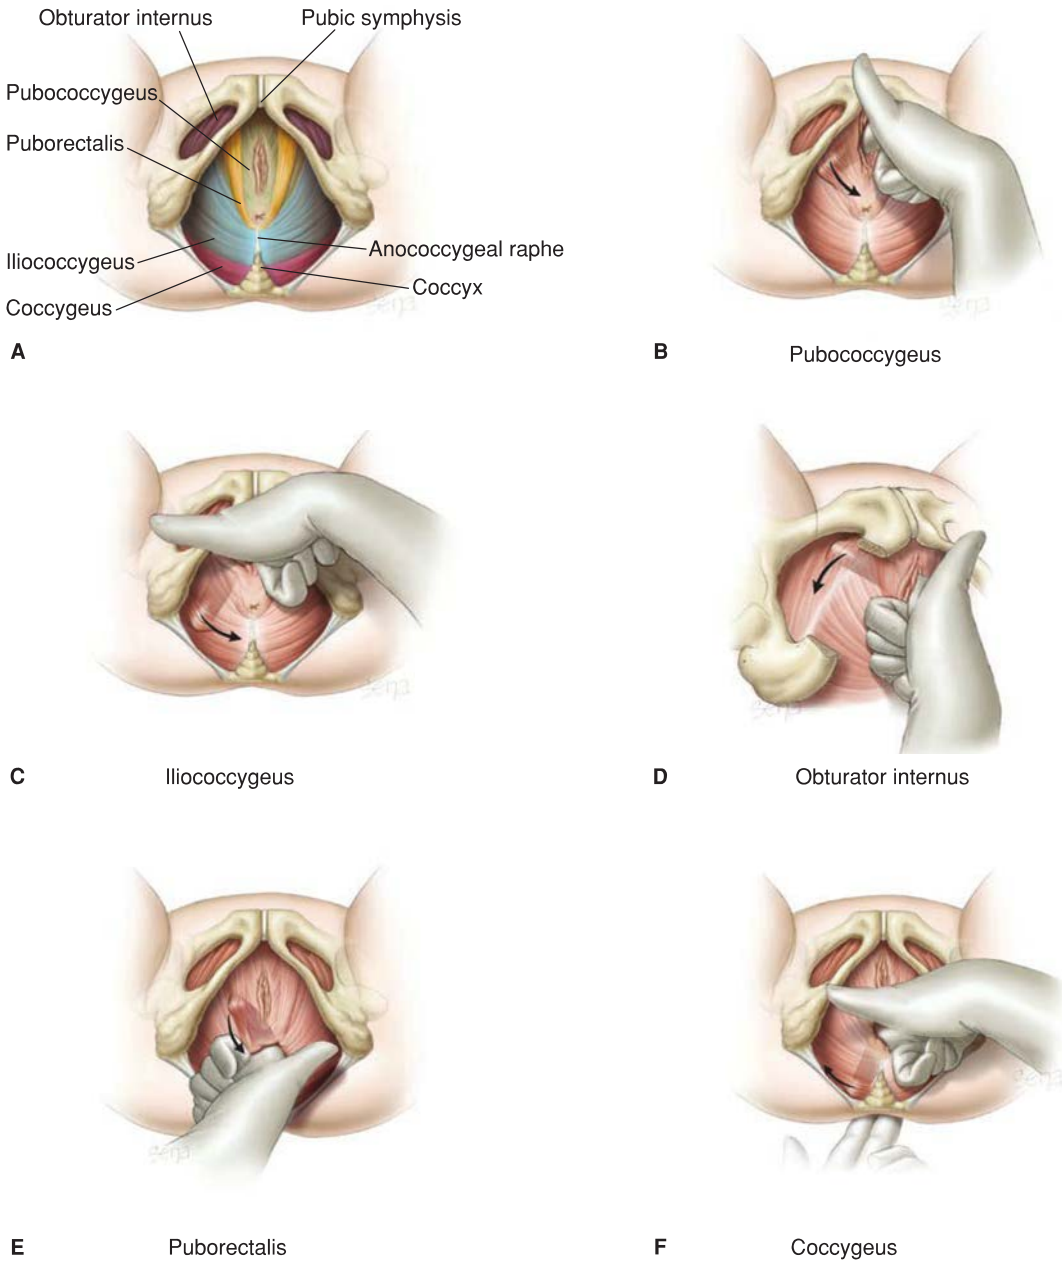

FIGURE 12-4 Pelvic floor muscle examination. (Reproduced with permission from Ms. Marie Sena.)

of the uterosacral ligaments are palpated. Tender nodularity has approximately 85-percent sensitivity and 5-percent specificity for the diagnosis of infiltrative endometriosis (Donnez, 1996). If pain follows gentle movement of the coccyx, then articular disease of the coccyx, termed *coccydynia*, is suspected. The importance of pelvic examination sequence cannot be overstated, as information from single-digit examination may be lost if preceded by bimanual examination.

Bimanual assessment of the uterus and adnexa investigates size, mobility, and tenderness. Specific benign pathologies of the uterus and adnexa are outlined in Chapters 9 and 10.

Rectal examination and rectovaginal palpation of the rectovaginal septum is included. Palpation of hard stool or hemorrhoids may indicate GI disorders, whereas nodularity of the rectovaginal septum may be found with endometriosis or neoplasia. Last, stool testing for occult blood may be performed during digital rectal examination at the initial visit.

Testing

For women with CPP, results from urinalysis and urine culture can indicate stones, malignancy, or recurrent urinary tract infection (UTI). Thyroid disease can affect physiologic functioning and may be found in those with bowel or bladder symptoms. Thus, serum thyroid-stimulating hormone (TSH) levels are commonly assayed. Diabetes can lead to neuropathy, and glucose levels can be assessed with urinalysis or serum screening.

Of radiologic imaging and endoscopy options, TVS is widely used by gynecologists to evaluate CPP for the same reasons described earlier (p. 256) (Hoyos, 2017). It is most effective for structural lesion identification. In those with suspected pelvic congestion syndrome, transvaginal color Doppler ultrasound is an adjunct to TVS (Phillips, 2014). Both TVS and MR imaging are recognized imaging modalities for diagnosing deep infiltrating pelvic endometriosis (Van den Bosch, 2018). In those with bowel symptoms, barium enema may indicate intraluminal or external obstructive lesions, malignancy, and diverticular or inflammatory bowel disease. However, flexible sigmoidoscopy and colonoscopy may offer more information because colonic mucosa can be directly inspected and biopsied.

Cystoscopy and laparoscopy can be employed, and patient symptoms will dictate their use. In those with symptoms of chronic pain and urinary symptoms, cystoscopy is often advised. For many women with no obvious cause of their CPP, laparoscopy can aid diagnosis (Cunanan, 1983; Kang, 2007). Laparoscopy allows direct identification and, in many cases, treatment of intraabdominal pathology. Therefore, laparoscopy is considered for CPP if initial evaluations are nondiagnostic.

Treatment

Nonpharmacologic Therapy

In many women with CPP, an identifying source is found and treatment is dictated by the diagnosis. However, in other cases, pathology may not be identified, and treatment is directed toward dominant symptoms.

Data addressing use of nonpharmacologic options for CPP are scarce, but benefits may be extrapolated from studies in other chronic pain syndromes. These therapies are typically low risk and may be advantageous in patients with multiple comorbidities, in those with drug intolerances or potential drug interactions, and for pain refractory to traditional therapies.

Of options, evidence supporting the role of dietary modification in CPP management is mainly limited to anecdotal reports or questionnaire-based surveys. Antiinflammatory, gluten-free, Paleo, and low fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (low FODMAP) diets are the most commonly cited as potentially beneficial for chronic pain.

Pelvic Floor Physical Therapy

This specialized physical therapy focuses on pelvic floor, hips, back, and abdominal wall muscles. Interventions are customized and often include a combination of therapeutic exercises, manual manipulation, trigger point or myofascial release, acupressure, patient education, biofeedback, and muscle coordination training (Bradley, 2017; Vandyken, 2017). Clinical experience supports the role of pelvic floor physical therapy (PFPT) for pelvic pain conditions, but high-quality evidence is limited. One small study showed reduced pain for women with pelvic floor myalgia (Zoorob, 2015).

Patients likely to benefit from PFPT are those with pain reproducible during pelvic floor, abdominal wall, or back muscle palpation or contraction. Another is the group with significant deconditioning as a result of pain avoidance behaviors (Till, 2017). Patients with CPP are ideally referred to a physical therapist with specialized expertise in PFPT for this indication (Polackwich, 2015).

Psychotherapy

Psychotherapy, in the form of cognitive behavioral therapy, counseling, group therapy, biofeedback, and mindfulness-based strategies can be used for CPP. In a randomized trial of women with endometriosis-associated pelvic pain, psychotherapy combined with somatosensory stimulation improved pain, dyschezia, and quality of life (Meissner, 2016). Mindfulness-based strategies promote pain acceptance and nonreactive awareness rather than attempts to control or decrease pain itself (Sturgeon, 2014). In one metaanalysis, this intervention improved pain acceptance and reduce depression rates in patients with chronic pain conditions (Veehof, 2016). Patients with CPP and concurrent depression or anxiety may especially benefit from mindfulness-based interventions (Sephton, 2007).

Neuromodulation

Peripheral neuromodulation involves delivering electrical stimulation to a sensory nerve, which is thought to suppress nociceptive processing of pain signals (Ellrich, 2005). No consensus defines the optimal target or location for neuromodulation for CPP (Hunter, 2018). Modalities include transcutaneous electric nerve stimulation (TENS), intravaginal electrical stimulation (IVES), sacral neuromodulation, and percutaneous tibial nerve stimulation (PTNS).

Of these, TENS using skin electrodes placed at the T10 dermatome was compared with placebo for CPP treatment. After 2 weeks, VAS pain scores improved with TENS (Sharma, 2017).

IVES uses an intravaginal probe to emit electrical impulses to stimulate muscle contraction. Several Food and Drug

Administration (FDA)-approved devices are available for pelvic floor muscle re-education or rehabilitation to treat stress, urge, or mixed urinary incontinence. IVES has also been studied for CPP using frequencies below the threshold to induce muscle contraction. Despite its widespread therapeutic use for CPP indications, few rigorous studies have evaluated its efficacy for CPP. In one randomized trial comparing IVES and placebo for CPP, IVES significantly reduced pain intensity after 5 weeks of treatment (de Bernardes, 2010). However, no long-term follow-up was incorporated in this study.

Sacral neuromodulation is FDA approved only for treatment of overactive bladder, urinary retention, and chronic fecal incontinence. The only currently available method for transforaminal sacral nerve access is the InterStim Neurostimulator, which is fully described and illustrated in Chapter 45 (p. 1111). InterStim has been used off label to treat refractory CPP, IC/BPS, and pudendal neuralgia. Evidence shows symptom relief still at 12 months (Hunter, 2018).

PTNS delivers electrical pulses through a needle to stimulate the afferent fibers of the tibial nerve that runs posterior to the medial malleolus and extends to the sacral nerve plexus. Although currently approved by the FDA for treatment of overactive bladder, only a few small studies have assessed PTNS efficacy for CPP. In one small randomized trial that compared PTNS with usual care for CPP, pain and physical functioning were significantly improved. Moreover, benefits were sustained after 6 months (Istek, 2014).

Pharmacologic Options

Pharmacologic options for management for CPP include analgesics, opioids, hormones, antidepressants, and antiepileptic drugs. CPP often has a visceral and neuropathic pain component. Accordingly, effective drug combinations often work peripherally and in the CNS (Carey, 2016).

Nonopioid analgesics include nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen. NSAIDs block inflammatory mediators through their inhibition of the cyclooxygenase enzyme, which reduces prostaglandin production. They are most useful if inflammatory states underlie the pain, and examples are found in Table 11-1 (p. 242). Acetaminophen has no antiinflammatory properties but may be useful as an analgesic, especially in patients with allergies or intolerances to NSAIDs.

Hormonal modulation may be most useful in patients with endometriosis-related CPP. However, pain from IC/BPS, IBS, inflammatory bowel disease, temporomandibular disorder, and migraine headaches may fluctuate with the menstrual cycle (Bharadwaj, 2015; LeResche, 2003; Powell-Boone, 2005). It follows that cycle suppression could improve symptoms. For this, off-label use of combination oral contraceptives (COCs) or progestin-only pills is a mainstay of hormonal modulation. Moreover, depot medroxyprogesterone acetate (DMPA), progestin implants, the levonorgestrel-releasing intrauterine system (LNG-IUS), and gonadotropin-releasing hormone (GnRH) agonists and antagonists are options. The oral GnRH antagonist elagolix is FDA-approved for the management of endometriosis-associated pain (Taylor, 2017).

Traditionally prescribed for neuropathic pain, gabapentin and pregabalin are anticonvulsants that act as calcium-channel blockers (Table 12-5). They have efficacy for nonspecific pain conditions and for fibromyalgia (Benzon, 2011). In gynecology, gabapentin has the most evidence of efficacy for women with CPP due to known gynecologic pathology (Lewis, 2016). Other anticonvulsants such as phenytoin, carbamazepine, and lamotrigine act by means of their sodium channel–blocking effects and are effective in many neuropathic pain conditions. However, studies evaluating their efficacy specifically for CPP are lacking.

Antidepressants can treat chronic pain syndromes, but limited evidence supports their usefulness for CPP. Of these, tricyclic antidepressants (TCAs) raise norepinephrine levels and are thought to modify descending pain pathways (Kremer, 2016). This makes them particularly effective for neuropathic pain, independent of their antidepressant effects. However, their use may be limited by significant anticholinergic side effects (Saarto, 2010). The serotonin- and norepinephrine-reuptake inhibitors (SNRIs) venlafaxine, duloxetine, and milnacipran have been studied in the management of chronic pain syndromes. Both TCAs and SNRIs at best modestly improve these pain syndromes, are often accompanied adverse effects that limit dosing and therapy, and have not been well studied for CPP. The benefits of selective serotonin-reuptake inhibitors (SSRIs) for anxiety and depression are well established. But, support of efficacy specifically for CPP is similarly lacking.

Opioid analgesia was reviewed in a 2018 metaanalysis of 96 randomized trials of patients with chronic noncancer pain. Opioid use was associated with significant but small improvements in pain and physical functioning compared with placebo. Comparisons of opioids with nonopioid alternatives (NSAIDs, TCAs, anticonvulsants) suggest that pain and physical functioning benefits may be similar, although the evidence was considered low to moderate quality (Busse, 2018).

In response to high rates of opioid use disorders in the United States, the Centers for Disease Control published guidelines in 2016 for the prescription of opioids for chronic nonmalignant pain (Nicol, 2017). These recommendations were based on three primary tenets. First, no evidence shows long-term improvement in function or pain between opioid and nonopioid alternatives. Second, opioid harms include overdose, opioid use disorder, and motor vehicle injuries. Last, nonpharmacologic and nonopioid pharmacologic treatments offer similar pain relief and less associated harm (Valentine, 2018).

Surgery

Hysterectomy and bilateral salpingo-oophorectomy (BSO) at times may serve as definitive management if thorough evaluation is complete and conservative therapies have failed. For many women with CPP, hysterectomy is effective in resolving pain and improving quality of life (Hartmann, 2004; Stovall, 1990). However, pain may not be resolved in a significant number. For example, one prospective study assessed 308 women for 1 year after hysterectomy performed for CPP. Of these, 75 percent had complete discomfort resolution, 21 percent had persistent but improved pain, and 5 had unchanged or worsening pain. Pain may persist despite hysterectomy more commonly in women who are <30 years, have mental illness, or have no identifiable pelvic pathology (Gunter, 2003). Almost

TABLE 12-5. Antidepressants and Antiseizure Drugs Used in Chronic Pain Syndromes

Drug (Brand name)	Dosage	Side Effects
ANTISEIZURE DRUGS		
Gabapentin (Neurontin)	100–300 mg at bedtime; increase by 100 mg every 3 days up to 1800 to 3600 mg per day taken in divided doses three times daily	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain
Pregabalin (Lyrica)	150 mg at bedtime for diabetic neuropathy; 300 mg twice daily for postherpetic neuralgia	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain
Lamotrigine (Lamictal)[a]	50 mg per day; increase by 50 mg every 2 weeks up to 400 mg per day	Dizziness, constipation, nausea; rarely, life-threatening rashes
Carbamazepine (Tegretol)	200 mg per day; increase by 200 mg per week up to 400 mg three times daily (1200 mg per day)	Dizziness, diplopia, nausea, aplastic anemia
Phenytoin (Dilantin)[a]	100 mg at bedtime; increase weekly up to 500 mg at bedtime	Blood dyscrasias, hepatotoxicity
ANTIDEPRESSANTS		
Tricyclic antidepressants		Dry mouth, constipation, urinary retention, sedation, weight gain
Amitriptyline (Elavil)[a] Imipramine (Tofranil)[a]	For both, 10–25 mg at bedtime; increase by 10–25 mg per week up to 75–150 mg at bedtime or a therapeutic drug level	Tertiary amines have greater anticholinergic side effects
Desipramine (Norpramin)[a] Nortriptyline (Pamelor)[a]	For both, 25 mg in the morning or at bedtime; increase by 25 mg per week up to 150 mg per day or a therapeutic drug level	Secondary amines have fewer anticholinergic side effects
SNRIs		
Venlafaxine (Effexor)[a]	37.5 mg per day; increase by 37.5 mg per week up to 225 mg per day	Nausea, sweating, sedation, dry mouth, anorexia, constipation, sweating
Duloxetine (Cymbalta)	60 mg once daily	
Milnacipran (Savella)	12.5 mg once daily and then escalate every few days through 12.5 mg and 25 mg twice daily to reach 50 mg twice daily	
SSRIs		
Fluoxetine (Prozac)[a] Paroxetine (Paxil)[a]	For both, 10–20 mg per day; up to 80 mg per day for fibromyalgia	Nausea, sedation, decreased libido, sexual dysfunction, headache, weight gain

[a]Not approved by the Food and Drug Administration for treatment of neuropathic pain.
SNRI = Serotonin- and norepinephrine-reuptake inhibitor; SSRI = Selective serotonin-reuptake inhibitor.

40 percent of women with no identified pelvic pathology will have persistent pain after hysterectomy (Hillis, 1995).

Failure of hysterectomy to relieve pain may be multifactorial. First, visceral reflexes may produce multiple pain syndromes within the same patient. Second, hysterectomy does not address nongynecologic etiologies for pelvic pain. Last, pain from IC/BPS, pelvic floor myofascial syndrome, or musculoskeletal disorders may worsen following surgery due to its potentially negative effects on innervation, musculature, or vasculature.

Accordingly, before hysterectomy is considered, efforts to accurately diagnose CPP causes and to conservatively manage pain are first exhausted. Women are given reasonable expectations for symptom relief from hysterectomy and informed of the potential for persistent or worsening pain. As with any operation, the anticipated benefits should outweigh potential risks.

Specific Causes of CPP

Pelvic Adhesions

Adhesions are fibrous connections that vary in vascularity and thickness between opposing organ surfaces or between an organ and abdominal wall. These develop secondarily and promoters

include previous surgery, prior intraabdominal infection, and endometriosis. Less commonly, inflammation from radiation, chemical irritation, or foreign-body reaction may be causes. Pain is typically aggravated by sudden movement or intercourse. In those with pain, adhesions are believed to stretch the peritoneum or organ serosa as it moves (Demco, 2004; Suleiman, 2001).

These fibrous connections are common, and in laparoscopies performed for CPP, adhesions are found in approximately one quarter of cases (Howard, 1993). However, not all adhesive disease creates pain (Thornton, 1997).

To diagnose these, a history of prior surgeries and pain with abrupt movement are suggestive. Adhesions are poorly imaged. Although not used routinely, dynamic sonography techniques that push the transducer to incite movement or tethering between organs can be informative in some cases (Ayachi, 2018; Nezhat, 2014).

Surgical lysis is often used to treat affected women with associated pain (Fayez, 1994; Steege, 1991; Sutton, 1990). However, two randomized studies comparing adhesion lysis with expectant management found no difference in pain scores after 1 year (Peters, 1992; Swank, 2003). Others who support the continued judicious use of adhesiolysis in the treatment of pelvic pain question the statistical methods used in these studies (Roman, 2009). When performed, adhesiolysis is associated with a significant risk of adhesiogenesis, especially in cases involving endometriosis (Parker, 2005). Moreover, actual adhesive disease is often not reliably confirmed preoperative. Thus, the decision to pursue laparoscopic adhesiolysis is individualized. Pain-relief benefits are balanced against laparoscopy risks and the risk for new adhesion formation with surgery. Techniques to minimize adhesion formation are described in Chapter 40 (p. 855).

Ovarian Remnant Syndrome and Ovarian Retention Syndrome

After oophorectomy, remnants of an excised ovary may create symptoms that are termed *ovarian remnant syndrome*. Distinction is made between this syndrome and *ovarian retention syndrome*. Ovarian retention syndrome involves symptoms stemming from an ovary intentionally left at the time of previous gynecologic surgery (El Minawi, 1999). Although differentiated by the amount of ovarian tissue involved, both syndromes have nearly identical symptoms and are diagnosed and treated similarly.

Although an uncommon cause of CPP, women with symptomatic ovarian remnants most typically complain of chronic or cyclic pain or dyspareunia. Those with BSO performed for endometriosis may be at particular risk (Kho, 2012). The onset of symptoms is variable and may begin years following surgery (Nezhat, 2005). Women with these syndromes may have a pelvic mass palpable on bimanual examination. Sonography is often informative. In those with remnants, ovaries may be identified in some cases by a thin rim of ovarian cortex surrounding a coexistent ovarian cyst (Fleischer, 1998). Indeterminate cases may require CT or MR imaging. In cases in which ureteral compression is suspected, radiographic or CT pyelography or MR imaging may be indicated. Laboratory testing, specifically follicle-stimulating hormone (FSH) levels, can aid diagnosis in reproductive-aged women with prior BSO. If these levels lie in the premenopausal range, then retained ovarian tissue is likely (Magtibay, 2005).

Although medical treatment has included hormonal manipulation to suppress functioning tissue, surgical excision is required in most symptomatic cases (Lafferty, 1996). Because the ureter or bladder is commonly intimately involved with adhesions encasing a remnant, laparotomy is reasonable in some cases. However, surgeons with advanced skills in minimally invasive surgery can achieve successful outcomes (Nezhat, 2005; Zapardiel, 2012).

Pelvic Congestion Syndrome

Retrograde blood flow through incompetent valves can often create tortuous, congested ovarian or pelvic veins. Chronic pelvic ache, pressure, and heaviness may result and is termed *pelvic congestion syndrome* (Beard, 1988). Currently, it is not clear whether congestion results from mechanical dilation, ovarian hormonal dysfunction, or both. Higher rates of ovarian varicosities and pelvic congestion syndrome are noted in parous women. A mechanical theory describes a dramatic increase in pelvic vein diameter during late pregnancy that leads to ovarian vein valve incompetence and pelvic varicosities. Estrogen is implicated in pelvic congestion syndrome in that it acts as a venous dilator. Moreover, pelvic congestion syndrome resolves following menopause, and antiestrogenic medical therapy can be effective (Farquhar, 1989; Gangar, 1993). Most likely, both factors play roles. The cause of pain with pelvic congestion also is unclear, but greater vessel dilation, concomitant stasis, and release of local nociceptive mediators are suggested mechanisms.

Affected women may describe pelvic ache or heaviness that may worsen premenstrually, after prolonged sitting or standing, or following intercourse. During physical examination, tenderness at the junction of the middle and lateral thirds of a line drawn between the symphysis and ASIS (the ovarian point) or direct ovarian tenderness may be found. In addition, varicosities in the thigh, buttocks, perineum, or vagina may be associated (Venbrux, 1999).

To initially investigate suspected cases, TVS or CT or MR venography is recommended. Sonographic findings with applied Doppler include a dilated tortuous ovarian vein with a diameter $\geq$6 mm, slow blood flow $\leq$3 cm/s, and a dilated arcuate vein in the myometrium that communicates to the pelvic varicosities (Fig. 12-5) (Park, 2004). With positive findings, retrograde ovarian and internal iliac venography is preferred if intervention is planned (Gloviczki, 2011). Diagnostic laparoscopy also can identify varicosities. However, because all these modalities are performed while a woman is supine or in Trendelenburg position, varicosities often decompress and may be missed. CO_2 insufflation pressure also contributes to the high false-negative rate of laparoscopy to diagnose pelvic varicosities.

Common treatments for pelvic congestion syndrome are hormonal suppression, ovarian vein embolization, or hysterectomy with BSO. First, medical treatment with medroxyprogesterone acetate, 30 mg orally daily, or with a GnRH agonist is effective for some women with pelvic congestion syndrome. Notably, symptoms typically recur after medication

FIGURE 12-5 Color Doppler transvaginal image of tortuous and dilated pelvic vessels in the right adnexa in a patient with chronic pelvic pain. (Reproduced with permission from Dr. Elysia Moschos.)

is discontinued (Reginald, 1989; Soysal, 2001). Alternatively, vessel embolization can be effective, and pain improves in 70 to 80 percent of treated women (Hansrani, 2015). Last, in one study of 36 women who underwent hysterectomy and BSO for pelvic congestion syndrome with intractable pelvic pain, 12 of 36 had residual pain at 1 year (Beard, 1991). However, only one patient had pain that affected her daily life, and authors concluded that pain and quality-of-life scores were improved. Importantly, none of these options is definitive, and evidence-based studies supporting their efficacy are limited.

DYSMENORRHEA

Cyclic pain with menstruation is common and accompanies most menses (Weissman, 2004). This pain is classically described as cramping and is often accompanied by low backache, nausea and vomiting, headache, or diarrhea. The term *primary dysmenorrhea* describes cyclic menstrual pain without an identifiable associated pathology, whereas *secondary dysmenorrhea* frequently complicates endometriosis, leiomyomas, PID, adenomyosis, endometrial polyps, and menstrual outlet obstruction. For this reason, secondary dysmenorrhea may be associated with other gynecologic symptoms, such as dyspareunia, dysuria, abnormal bleeding, or infertility.

Compared with secondary dysmenorrhea, primary dysmenorrhea more commonly begins shortly after menarche. Pain characteristics, however, typically fail to differentiate between the two types, and primary dysmenorrhea is usually diagnosed following exclusion of known associated causes.

When other factors are removed, primary dysmenorrhea equally affects women regardless of race and socioeconomic status. However, increased pain duration or severity is positively associated with earlier age at menarche, long menstrual periods, smoking, and greater body mass index (BMI). In contrast, parity appears to improve symptoms (Harlow, 1996; Sundell, 1990).

Pathophysiologically, prostaglandins are implicated in dysmenorrhea. During endometrial sloughing, endometrial cells release prostaglandins as menstruation begins. Prostaglandins stimulate myometrial contractions and ischemia. Women with more severe dysmenorrhea have higher levels of prostaglandins in their menstrual fluid, and these levels are highest during the first 2 days of menstruation. Prostaglandins are also implicated in secondary dysmenorrhea. However, anatomic mechanisms also are suspected, depending on the type of accompanying pelvic disease.

Diagnosis

In women with menstrual cramps and no other associated findings or symptoms, no additional evaluation may be initially required, and empiric therapy can be prescribed (Proctor, 2006). If pelvic evaluation is incomplete due to body habitus, TVS may be informative to exclude structural pelvic pathology. If symptoms or physical examination suggest a specific source for secondary dysmenorrhea, evaluation is directed to confirm this suspicion.

Treatment

Of options, NSAIDs are often preferred. Because prostaglandins are suspected in the genesis of dysmenorrhea, NSAID administration is logical, and studies support their use (Marjoribanks, 2015). These drugs and their dosages are found in Table 11-1 (p. 242).

Steroid hormone contraception leads to endometrial atrophy and in turn to lower endometrial prostaglandin levels. Of choices, COCs are believed to improve dysmenorrhea by lowering prostaglandin production (Brill, 1991; Wong, 2009). In addition, extended or continuous administration of COCs, described in Chapter 5 (p. 122), may be helpful for women with pain not controlled by the traditional cyclic pill schedule (Sulak, 1997). Progestin-only contraceptives also are used for dysmenorrhea. Namely, the LNG-IUS, DMPA, or progestin-releasing implant is a reasonable choice (Lindh, 2013).

GnRH agonists, GnRH antagonists, and androgens are other options. The estrogen-lowering effects of these lead to endometrial atrophy and diminished prostaglandin production. Although GnRH agents and androgens such as danazol lessen dysmenorrhea, their substantial side effects preclude their routine and long-term use. A fuller discussion of these agents and their side effects is found in Chapter 11 (p. 243).

Cases of dysmenorrhea refractory to conservative management are unusual, and in such instances, surgery may be indicated. Hysterectomy is effective in treating dysmenorrhea, but those desiring future fertility may decline. For these women, presacral neurectomy (PSN) can be considered.

PSN involves interruption of somatic pain fibers from the uterus that course within the superior hypogastric plexus (Fig. 38-13, p. 802). This procedure is performed by incising the pelvic peritoneum over the sacrum and then identifying and transecting the sacral nerve plexus. PSN is technically challenging and requires familiarity with operating in the presacral space. PSN has central pelvic effects and is most effective for dysmenorrhea. Success rates range from 60 to 75 percent (Chen, 1997; Lee, 1986; Zullo, 2003). However, surgery can be associated with long-term postoperative constipation and urinary retention. Infrequently, intraoperative hemorrhage may

be encountered from the middle sacral vessels, which run in the presacral space.

Laparoscopic uterosacral nerve ablation (LUNA) destroys nerve fibers that pass to the uterus through the uterosacral ligament. Current evidence does not support LUNA use for pelvic pain (Daniels, 2009, 2010; Proctor, 2005).

DYSPAREUNIA

Dyspareunia is defined as pain with intercourse. It is subclassified as *insertional*, that is, pain with vaginal entry, or *deep*, which is associated with deep penetration. Of insertional dyspareunia cases, most stem from vulvodynia, vulvitis, poor lubrication, or genitourinary symptoms of menopause (GSM), which is the new preferred term for vulvovaginal atrophy. Of deep dyspareunia cases, endometriosis, pelvic adhesions, and bulky leiomyomas are frequent causes. In many women, both insertional and deep dyspareunia may be present.

Additional terms include *primary dyspareunia*, which describes the onset of painful intercourse coincident with coitarche. *Secondary dyspareunia* is painful intercourse after a period of pain-free sexual activity. Sexual abuse, female genital mutilation, and congenital anomalies most frequently lead to primary dyspareunia, whereas sources of secondary dyspareunia are more varied. Last, dyspareunia is clarified as *generalized*, occurring in all episodes of intercourse, or as *situational*, associated with only specific partners or sexual positions. Changes in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) have merged dyspareunia and vaginismus into the term *genito-pelvic pain/penetration disorder* (American Psychiatric Association, 2013).

Dyspareunia is common, and in reproductive-aged women in the United States, the 12-month prevalence is 15 to 20 percent (Glatt, 1990; Laumann, 1999). Painful intercourse may be associated with vulvar, visceral, musculoskeletal, neurogenic, or psychosomatic disorders. Coexistent etiologies also may lead to similar symptoms. For example, women with vulvodynia in many cases have coexistent pelvic floor muscle spasm, both of which may cause dyspareunia (Reissing, 2005). Because of the frequent association between dyspareunia and CPP and frequent overlap of etiologies, physical examination and diagnostic testing often follow that for women with CPP (p. 258).

Diagnosis

During history taking, patients are questioned regarding associated symptoms such as vaginal discharge, vulvar pain, dysmenorrhea, CPP, dysuria, or scant lubrication. Onset of symptoms and their temporal association with obstetric delivery, pelvic surgery, sexual abuse, or menopause is often informative. In addition, dyspareunia may be found in those who breastfeed, presumably because of hypoestrogenism-derived vaginal atrophy seen with lactation (Buhling, 2006; Signorello, 2001). Psychosocial topics such as relationship satisfaction or depression also are covered. These elements and others related to female sexuality are fully discussed in Chapter 14.

Inspection of the vulva mirrors that for CPP. In particular, generalized erythema, episiotomy scars, or atrophy is sought. Erythema may indicate contact or allergic dermatitis or infection, particularly fungal infection. Accordingly, a historical inventory of potential skin irritants, microscopy of a saline-mixed vaginal discharge, vaginal pH testing, and vaginal cultures are performed. Specifically, a vaginal fungal culture may be required in some cases as several noncandidal species may be poorly detected if microscopic analysis is solely used (Haefner, 2005).

Some studies, but not all, have found a positive correlation between the degree of pelvic organ prolapse and dyspareunia (Burrows, 2004; Ellerkmann, 2001). If noted, its degree is assessed as described in Chapter 24 (p. 537).

Physical examination evaluates the distal, mid-, and proximal vagina. Evaluation may first begin with palpation of the Bartholin and paraurethral glands. Additionally, cotton-swab testing is used to map painful areas (Fig. 4-1, p. 93). Next, insertion of a single digit into the distal vagina may elicit vaginismus, that is, reflex contraction of the muscles associated with distal vaginal penetration (Basson, 2010). This contraction response is normal, but prolonged spasm of the bulbospongiosus, pubococcygeus, piriformis, and obturator internus muscles may cause pain. Spasm is thought to be a conditioned response to current or former physical pain.

With deeper digital examination, midvaginal pain may be triggered. This can be seen with IC/BPS or urethral diverticula, with congenital anomalies, or after radiation therapy or pelvic reconstructive surgeries.

Deep dyspareunia is more commonly caused by disorders that also cause CPP. Focal points of this examination are discussed on page 260. Similarly, diagnostic testing for deep dyspareunia in large part mirrors that for CPP. Urine and vaginal cultures may indicate infection, and radiologic imaging may reveal structural visceral disease.

Treatment

Resolution of dyspareunia is highly dependent on the underlying cause. For those with vaginismus, structured desensitization is effective. Patients gradually gain control in comfortably inserting dilators of increasing size into the introitus. Concurrent psychological counseling in such cases is often indicated. Poor lubrication may be countered with education directed toward adequate arousal techniques and use of external lubricants. Discussed in Chapter 22 (p. 496), estrogen cream or the selective estrogen-receptor modulator ospemifene (Osphena) will usually resolve GSM. Elagolix is FDA approved for endometriosis-related dyspareunia at doses of 200 mg bid for 6 months.

Surgery may be indicated for structural pathologies and may include ablation of endometriosis, lysis of adhesions, and restoration of normal anatomy. For those with dyspareunia confidently attributed to a retroverted uterine position, uterine suspension was shown to be effective, although studies were small (Perry, 2005).

UROLOGIC ETIOLOGIES

Infection

Recurrent UTIs are defined as two or more symptomatic infections in 6 months or three episodes in 1 year (Smith, 2018). In addition to acute treatment, continuous or postcoital antibiotic

prophylaxis or self-treatment for recurrences is an effective approach (Stamm, 1993). In postmenopausal women, topical vaginal estrogen alters the vaginal flora and significantly reduces the risk of UTI compared with placebo (Raz, 1993).

Dysuria and itching are prominent symptoms of infectious urethritis. This is commonly caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Mycoplasma genitalium*, and less commonly by *Trichomonas vaginalis*, *Gardnerella vaginalis*, *Ureaplasma urealyticum*, herpes simplex virus, and some adenoviruses (Hakenberg, 2017). Thus, a sexual history is important, and testing for these infections may be indicated depending on history and physical examination findings. Suitable testing methods for these are found in Chapter 3 (p. 65).

Urethral Diverticulum

Classic symptoms associated with urethral diverticula are known as the "3D's" (dysuria, dyspareunia, postvoid dribbling). Women may also note recurrent UTI, vaginal wall tenderness, frequency, urgency, and chronic pelvic or urethral pain (Baradaran, 2016; El-Nasher, 2016; Foley, 2011; Romanzi, 2000). Clinical evaluation and treatment of urethral diverticula are discussed in Chapter 26 (p. 582).

Lower Urinary Tract Stones

Vesical calculi represent 5 percent of urinary tract stones and typically result from foreign bodies, obstruction, or infection (Philippou, 2012). Women with prolapse may develop bladder stones from urethral obstruction and urinary stasis. Vesical calculi may also form after antiincontinence procedures due to suture or mesh in the lower urinary tract (Philippou, 2012; Schwartz, 2000). The most common symptoms are terminal dysuria, pain, incontinence, urgency, and frequency (Stav, 2012). Bladder stones can be detected by radiography, sonography, CT, or cystoscopy (Stav, 2012). Referral to a urogynecologist or urologist for further management is appropriate.

Other Causes

As discussed in Chapter 11, symptoms of urinary tract endometriosis may include colicky flank pain, recurrent UTIs, frequency, urgency, and bladder pain during voiding (Berlanda, 2009). Leiomyomas, discussed in Chapter 9, and midurethral slings for stress urinary incontinence, detailed in Chapter 45, both may cause chronic pain and urinary tract symptoms (Abouassaly, 2004; Langer, 1990). Patients with neoplastic lesions such as bladder cancer may present with dysuria, hematuria, pain, and recurrent UTIs (Henning, 2013).

Interstitial Cystitis/Bladder Pain Syndrome

This condition describes a symptom complex that encompasses bladder, urethral, and pelvic pain, as well as lower urinary tract symptoms. The American Urological Association considers IC and BPS to be synonymous, and defines it as "an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes" (Hanno, 2011). IC/BPS is estimated to affect 6.5 percent of women in the United States, and the condition is typically diagnosed after age 40 (Berry, 2011; Hanno, 2015).

The exact cause of IC/BPS is unknown. Two current theories focus on greater bladder mucosa permeability or mast cell activation. Glycosaminoglycans (GAG) are an important component of the mucin layer that covers and protects the bladder urothelium. One theory explains that IC/BPS symptoms originate from a defect in the protective bladder GAG component. This leads to increased permeability of the bladder mucosa to noxious agents (Parsons, 2007; Sant, 2007; Theoharides, 2001).

Diagnosis

IC/BPS is considered in women with unexplained CPP and voiding symptoms. By definition, it is a diagnosis of exclusion. Other conditions such as recurrent UTI, urethral diverticulum, bladder stone, endometriosis, leiomyomas, foreign bodies, and neoplasia can mimic IC/BPS. In one study, 45 percent of patients with an initial diagnosis of IC/BPS were found during further evaluation to have other common alternative diagnoses (Irwin, 2005).

Pain, including pelvic pressure and discomfort, is the hallmark symptom of IC/BPS. The pain is often related to bladder filling and associated with pain in the pelvis, lower abdomen, and back. Frequency and urgency also are typical complaints, but other symptoms include dyspareunia and postcoital ache. Symptoms may worsen premenstrually. Given the broad spectrum of triggers that include alcohol, caffeine, smoking, spicy foods, citrus fruits and juices, carbonated drinks, and potassium, patients may not relate exacerbation of their symptoms to these. Cranberry juice, frequently advised for UTI prevention, can acutely exacerbate pain from IC/BPS.

Single-digit vaginal examination in the patient with IC/BPS may demonstrate urethral or anterior vaginal/bladder base tenderness and pelvic floor hypertonus, tenderness, or trigger points. Laboratory examination classically includes urinalysis and culture, and unevaluated microhematuria typically prompts cytology, especially in smokers, to exclude urinary tract neoplasia. Cystoscopy and urodynamic studies may add clarity to complex presentations or exclude of other entities that mimic IC/BPS. However, consensus on cystoscopic or urodynamic criteria for IC/BPS is lacking (Hanno, 2011). Cystoscopically, *Hunner ulcers* are reddish-brown mucosal lesions with small vessels radiating toward a central scar. These ulcers are rare but considered diagnostic for IC. The more common finding is *glomerulations,* which are small petechiae or submucosal hemorrhages. However, these may be present in patients without IC/BPS symptoms and undergoing cystoscopy for other indications (Waxman, 1998). Urodynamic testing may reveal sensory urgency at low bladder volumes, decreased compliance, and diminished capacity. The potassium sensitivity test (PST) indicates greater urothelial permeability but is painful and may trigger a severe symptom flare. Moreover, a negative result does not eliminate suspicion for IC/BPS. In one study, 25 percent of patients meeting strict IC criteria had a negative PST result (Parsons, 1998).

Diagnosing IC/BPS can be challenging given its broad symptom spectrum, its frequent association with other pelvic

pain syndromes, and its symptoms that overlap with other pain disorders. Moreover, uniform consensus on diagnostic criteria is lacking. Thus, the diagnosis of IC/BPS remains clinical. Not surprisingly, misdiagnosis, underdiagnosis, or delayed diagnosis of IC/BPS is common.

Treatment

A multidisciplinary approach to treatment should be emphasized (Nickel, 2011). The American Urological Association has provided evidence-based guidelines for IC/BPS management (Hanno, 2011, 2015). First-line treatment provides patient education and behavioral modification, especially avoidance of bladder irritants. In one prospective study, dietary manipulation improved symptoms and quality of life in patients with IC/BPS (Oh-Oka, 2017).

Second-tier options are pharmacologic agents or pelvic floor physical therapy to resolve trigger points or pelvic floor hypertonus. One small randomized trial showed reduced pain in affected women (FitzGerald, 2012). Suitable oral agents include amitriptyline, cimetidine, hydroxyzine, or pentosan polysulfate sodium (Elmiron). The choice is typically provider dependent and is influenced by patient characteristics, previous treatments, provider experience, and perhaps cost. Pentosan polysulfate sodium is a weak anticoagulant, but its mechanism of action for IC/BPS is unknown. Elmiron is FDA-approved for this indication, and the dosage is 100 mg three times daily. Doses ideally avoid meals. Also, intravesical therapy may consist of direct bladder instillation of heparin, lidocaine, or dimethyl sulfoxide (DMSO).

For patients who do not respond, third-line treatments include cystoscopy coupled with short-duration, low-pressure bladder distention and fulguration of Hunner ulcers. FDA approval is lacking for treatment with cyclosporin A, intradetrusor botulinum toxin A, sacral neuromodulation, and pudendal nerve stimulation. This last is similar to sacral neuromodulation, but instead the implanted electrode stimulates the pudendal nerve (Hunter, 2018). These third-tier methods may be considered in patients who fail to respond to other therapies. Last, major surgery such as cystoplasty or urinary diversion is performed rarely for carefully selected patients in whom all other therapies have failed to provide adequate symptom control.

Treatments that are not recommended due to poor efficacy or unacceptable adverse events include long-term antibiotic use, intravesical bacillus Calmette-Guérin or resiniferatoxin, high-pressure or long-term hydrodistension, and long-term oral corticosteroids (Hanno, 2011).

GASTROINTESTINAL DISEASE

GI disease is often found to underlie CPP and causes may be organic or functional (see Table 12-2). Thus, initial screening may follow that for CPP. However, symptoms such as fever, GI bleeding, weight loss, anemia, and abdominal mass will prompt a stronger search for organic pathology. Investigations may include sigmoidoscopy or colonoscopy to exclude inflammation, diverticula, or tumors. For those with diarrhea, stool examination for leukocytes or for ova and parasites may be indicated. Moreover, serologic testing for celiac disease can be valuable. When indicated, TVS may aid in distinguishing GI from gynecologic pathology.

Colonic Diverticular Disease

Colon diverticula are small defects in the muscular layer of the colon through which colonic mucosa and submucosa herniate. Diverticular disease is common and typically affects the sigmoid or descending colon. Recurrent or chronic disease can lead to CPP (Morris, 2014). Chronic symptoms include abdominal pain that localizes to the left lower quadrant, obstipation, and rectal fullness. More seriously, diverticula may cause acute or chronic GI bleeding or may become infected. Clinically, infection can be difficult to distinguish from PID or tuboovarian abscess. In these cases, CT is the preferred imaging technique and has sensitivity for diagnosis of 94 percent and specificity of 99 percent (Lameris, 2008).

Chronic diverticular disease is usually treated with a high-fiber diet and long-term suppressive therapy with antibiotics. With acute severe infection, hospitalization, parenteral antibiotics, surgical or percutaneous abscess drainage, or partial colectomy may be required. Suspected rupture of a diverticular abscess with peritonitis is an indication for immediate surgical exploration (Morris, 2014).

Celiac Disease

This is an inherited autoimmune intolerance to gluten, which is a component of wheat, barley, or rye. In affected individuals, gluten ingestion creates an immune-mediated reaction that damages the small intestine mucosa and leads to varying degrees of malabsorption. Thus, treatment dictates a gluten-free diet for life (Rubio-Tapia, 2013). Celiac disease is common, and its incidence in the general population approaches 1 percent (Green, 2007).

The most common symptoms are abdominal pain and diarrhea. Other findings include weight loss, osteopenia, and fatigue from anemia, all of which stem from malabsorption. In addition, celiac disease has been associated with infertility, although the mechanism is not understood (Tersigni, 2014).

Celiac disease is suspected in those with characteristic findings and in those with a family history of the disorder. Diagnosis requires both duodenal biopsy and a positive response to a gluten-free diet. However, many physicians will screen with noninvasive serologic tests. Of these, testing for IgA antitissue transglutaminase antibodies is preferred. For this, patients maintain a gluten-containing diet during testing (Rubio-Tapia, 2013).

Functional Bowel Disorders

This group of functional disorders has symptoms attributable to the lower GI tract, and definitions are periodically updated. Those listed in Table 12-6 reflect Rome IV criteria (Drossman, 2016a,b). The diagnosis of these functional disorders always presumes the absence of a structural or biochemical explanation for symptoms.

Irritable Bowel Syndrome

This functional bowel disorder is defined as abdominal pain related to defecation and is associated with a change in bowel

TABLE 12-6. Functional Bowel Disorders and Definitions[a]

Irritable bowel syndrome (IBS)	Recurrent abdominal pain on average at least 1 day/week in the last 3 months associated with 2 or more of the following: (1) related to defecation; (2) associated with a change in stooling frequency; (3) associated with a change in form of stool
Functional abdominal bloating/distention	Must include *both* of the following: (1) recurrent bloating or distention on average at least 1 day/week; (2) insufficient criteria for a diagnosis of IBS or other functional GI disorder
Functional constipation	Must include *two or more* of the following: (1) straining during >25% of defecations; (2) lumpy or hard stools in >25% of defecations; (3) sensation of incomplete evacuation in >25% of defecations; (4) sensation of anorectal obstruction/blockage in >25% of defecations; (5) manual maneuvers to aid >25% of defecations; (6) fewer than three defecations per week Loose stools are rarely present without the use of laxatives Criteria insufficient for IBS
Functional diarrhea	Loose or watery stools without pain, occurring in >25% of stools
Unspecified functional bowel disorder	Bowel symptoms not attributable to an organic etiology that do not meet criteria for the previously defined categories
Opioid-induced constipation	New or worsening constipation related to opioid therapy with two of more of the same required criteria for functional constipation Loose stools are rarely present without the use of laxatives

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.
GI = gastrointestinal.
From Drossman, 2016b; Lacy, 2016.

habits. Criteria further mandate that symptoms are present for the last 3 months with symptom onset at least 6 months before diagnosis (Lacy, 2016). Subtypes are divided by the predominant stool pattern and include constipative, diarrheal, and mixed categories. Although defining criteria are listed in Table 12-6, other symptoms that support the diagnosis include straining, defecatory urgency, feeling of incomplete evacuation, passing mucus, and bloating.

IBS is common, and its general population prevalence approximates 10 percent (Canavan, 2014; Lovell, 2012). The prevalences of diarrhea-predominant and constipation-predominant IBS are equivalent, but constipation-predominant IBS may be more common in women (Saito, 2002, Lovell, 2012).

The pathophysiology of IBS is complex, and neural, hormonal, genetic, environmental, and psychosocial factors are variably involved (Drossman, 2002). The primary mechanism of IBS, however, is thought to stem from poorly regulated interactions between the CNS and the enteric nervous system (ENS). Such brain-gut dysfunction may eventually cause alterations of GI mucosal immune response, intestinal motility and permeability, and visceral sensitivity. In turn, these produce abdominal pain and altered bowel function (Mayer, 2008). Specifically, serotonin (5-hydroxytryptamine, 5-HT) is involved with regulating intestinal motility, visceral sensitivity, and gut secretion and is implicated in IBS (Atkinson, 2006; Gershon, 2005).

For young patients who have typical IBS symptoms and no organic disease symptoms, few tests are required. Testing is individualized, and factors that typically prompt greater evaluation include older patient age, longer duration and greater severity of symptoms, absent psychosocial factors, organic disease symptoms, and family history of GI disease.

Treatment. Nonpharmacologic approaches may improve symptoms. First, no specific diet suffices for all patients, but foods known to trigger symptoms are logically avoided. Combination probiotics in general improve global IBS symptoms, bloating, and flatulence, although data limit recommendation of preferred species (Ford, 2014a,c).

Drug therapy is directed toward dominant symptoms. For those with constipation-dominant IBS, commercial soluble fiber analogues or psyllium husk may help if increased dietary fiber is unsuccessful (Bijkerk, 2009). Of these, psyllium husk is gradually titrated to improve tolerability to a dosage of 3 to 5 g orally twice daily. Of note, dietary fiber is effective in treating constipation but is not effective for diarrhea-dominant IBS or for IBS-associated pain (Ruepert, 2011).

Of medical options, linaclotide (Linzess), a guanylate cyclase agonist, enhances fluid secretion and transit time (Chey, 2012b; Rao, 2012). It is taken orally as a 290-μg capsule once daily. Alternatively, lubiprostone (Amitiza) is a GI chloride-channel activator that is taken orally twice daily as an 8-μg capsule. It also enhances intestinal fluid secretion to improve intestinal motility (Chey, 2012a; Drossman, 2009).

For those with diarrhea-dominant symptoms, treatments often strive to slow bowel motility because as substances stay longer in the gut, more water is absorbed from fecal matter to bulk stools. Goals are improved abdominal pain and stool consistency. Indirect evidence supports loperamide (Imodium), 2 mg orally once or twice daily (Trinkley, 2014; Weinberg, 2014). Eluxadoline (Viberzi) acts peripherally on bowel opioid receptors to reduce visceral hypersensitivity without completely disrupting intestinal motility. It improves IBS symptoms when a 100-mg dose is taken twice daily (Lembo, 2016). Rifaximin (Xifaxan) is an oral, nonsystemic

antibiotic that targets the gut microbiome to improve symptoms (Pimentel, 2011). Last, for those with severe diarrhea, alosetron (Lotronex), a selective serotonin 5-HT_3-receptor antagonist, interacts with ENS neuron receptors to aid IBS symptoms (Camilleri, 2000; Chey, 2004). However, due to cases of ischemic colitis associated with its use, alosetron is now available but providers are encouraged to participate in a modified risk evaluation and mitigation strategy (REMS) program that provides product updates when needed (Chang, 2006; Food and Drug Administration, 2016).

For patients with pain secondary to bowel spasm, antispasmodic agents decrease intestinal smooth muscle activity and are thought to improve abdominal discomfort. Agents available in the United States include dicyclomine (Bentyl) and hyoscyamine sulfate (Levsin). Dicyclomine is begun at 20 mg orally four times daily and increased after 1 week to 40 mg. Hyoscyamine sulfate is dosed at 0.25 to 0.5 mg orally daily and can be increased as needed up to four times daily. Although having benefits for IBS, the anticholinergic side effects of these agents often limit their long-term use (Ruepert, 2011; Schoenfeld, 2005). Peppermint oil, another effective antispasmodic, can be taken orally as over-the-counter capsules at dosages of 550 mg once daily or 187 mg three times daily (Khanna, 2014).

Tricyclic antidepressants may help patients with IBS both by an anticholinergic effect on the gut and by their mood-modifying action. TCAs may slow intestinal transit time and can be effective in treatment of diarrhea-dominant IBS (Hadley, 2005). Last, psychological or behavioral treatments may help some patients (Ford, 2014b).

Functional Anorectal Pain

Proctalgia fugax, levator ani syndrome, and unspecified functional anorectal pain are the three types of functional anorectal pain disorders described by Rome IV criteria (Rao, 2016). The term *chronic proctalgia* is excluded from the new classification.

Levator ani syndrome usually presents as a pressure or dull ache in the upper rectum that is often worse with sitting than with standing or lying. Four criteria are: (1) chronic or recurrent rectal pain or aching, (2) episodes lasting ≥30 minutes, (3) exclusion of organic rectal pain causes, and (4) tenderness during traction on the puborectalis muscle. These four must be present for the last 3 months and symptom onset should be at least 6 months before diagnosis. A diagnosis of *unspecified functional anorectal pain* can be made when the first three of these are present.

The levator ani muscles, including their supporting fascia, overlying parietal peritoneum, and intimately associated visceral peritoneum, are connected by common sensory nerves to the spinal cord. These are thought to provide the basis for viscerosomatic convergence (Spitznagle, 2014). Some suggest that pain stems from trigger points, described subsequently, in the levator ani muscles.

For levator ani syndrome treatment, biofeedback is preferred, but anal canal electrical stimulation or levator ani muscle massage is an option. Adjuvant treatments include warm sitz baths and medicines such as NSAIDs, other analgesics, muscle relaxants, and tranquilizers (Hull, 2009).

In contrast, *proctalgia fugax* presents as sudden, severe rectal pain, unrelated to defecation, that lasts for a few seconds to a few minutes and then completely disappears. Pain may disrupt normal activities and may awaken a patient from sleep. But, episodes rarely occur more than five times a year. Diagnosis is based on its characteristic symptoms and exclusion of organic anorectal or pelvic pathology (Rao, 2016). Proctalgia fugax is typically managed with explanation of the condition and reassurance.

MUSCULOSKELETAL ETIOLOGIES

Clinical syndromes involving the muscles, nerves, and skeletal system of the lower abdomen and pelvis are frequently encountered but often overlooked by gynecologists. Importantly, unrecognized musculoskeletal pain may lead to unnecessary surgery or promote development of pelvic pain syndromes.

Hernia

Defects in the anterior abdominal wall or femoral fascia can lead to herniation of bowel or other intraabdominal contents through these rents. Such herniation can create pain locally at the defect site or cause referred pain along the distribution of a compressed sensory nerve. Moreover, if blood supply to the contents is acutely compromised, then bowel obstruction or ischemia will require surgical intervention. Hernias that involve the anterior abdominal wall and pelvic floor are most commonly associated with CPP.

Hernias may develop at sites of inherent anatomic weakness, which may be congenital or acquired. Conditions that raise intraabdominal pressure such as pregnancy, ascites, peritoneal dialysis, and chronic cough are known risk factors. Of types, ventral hernias derive from fascial defects typically occurring in the midline and may develop at prior incision sites (Fig. 12-6). Umbilical hernias originate from umbilical ring weakness. Spigelian hernias are rare and develop along the lateral rectus abdominis muscle border, especially at this border's intersection with the arcuate line. Indirect inguinal hernias are those in which abdominal contents herniate through the internal inguinal ring and into the inguinal canal. Contents may then exit the external inguinal ring (Fig. 12-7). In contrast, contents of a direct inguinal hernia bulge directly through a fascial defect within the Hesselbach triangle.

For diagnosis, patients with CPP or abdominal pain ideally are examined while standing and also during Valsalva maneuver. Small ventral, umbilical, or incisional hernias may be repaired by gynecologic surgeons. In these cases, the hernia sac is excised and fascia reapproximated. Patients with larger hernias, which usually require mesh placement, or with hernias in the inguinal area are typically referred to a general surgeon.

Myofascial Pain Syndrome

Primary musculoskeletal conditions can lead to CPP (see Table 12-2). In other cases, secondary myofascial pain syndromes can originate from endometriosis, IC/BPS, or IBS. Such chronic visceral inflammatory conditions can create pathologic changes in nearby muscles and/or nerves to cause abdominal

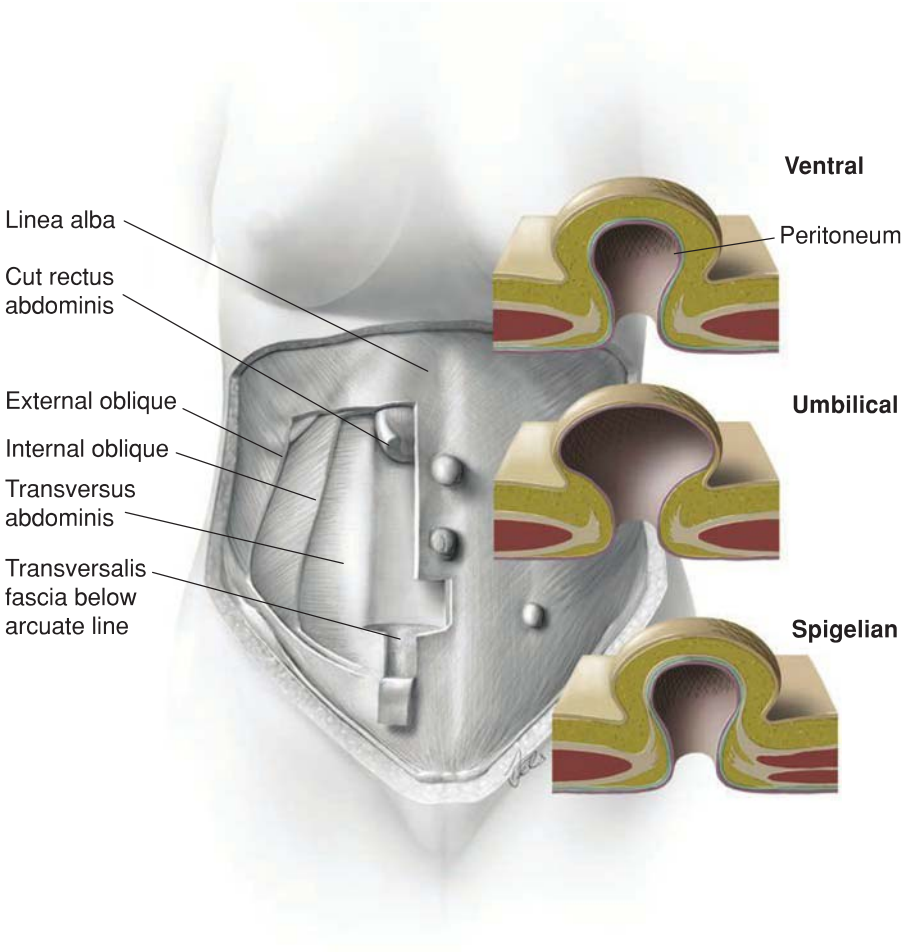

FIGURE 12-6 Hernias that may involve the anterior abdominal wall. (Reproduced with permission from Mr. T. J. Fels.)

FIGURE 12-7 Indirect and direct inguinal hernias and femoral hernia. (Reproduced with permission from Mr. T. J. Fels.)

wall or pelvic floor pain. With myofascial pain, a hyperirritable area within a muscle promotes persistent fiber contraction (Simons, 1999). The primary reactive area within the muscle is termed a *trigger point (TrP)* and is identified as a palpable taut, ropy band.

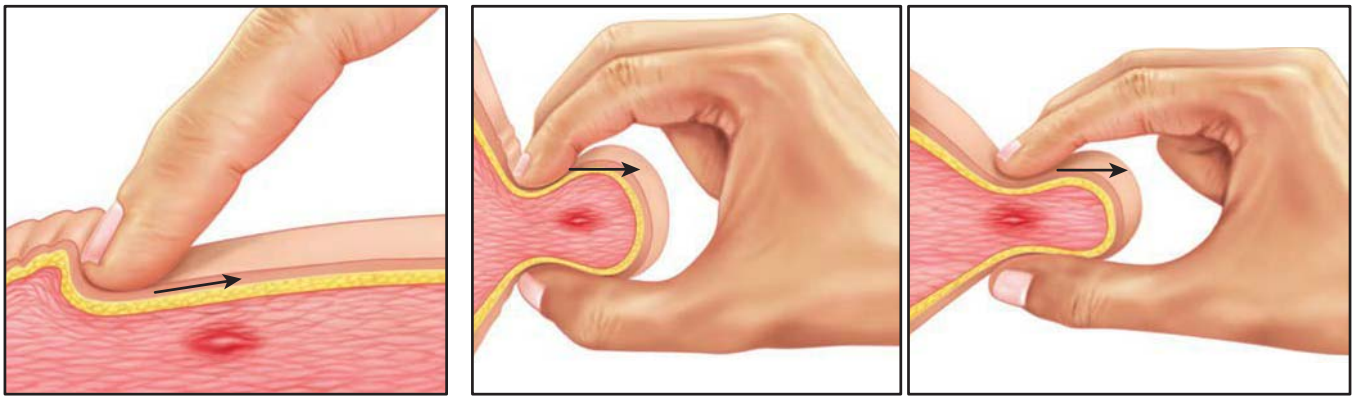
TrPs are thought to form as the end point of a metabolic crisis within a muscle. Dysfunction of a neuromuscular endplate can lead to sustained acetylcholine release, persistent depolarization, sarcomere shortening, and creation of a taut muscle band. Affected fibers compress capillaries and decrease local blood flow. The resulting ischemia leads to release of substances that activate peripheral nerve nociceptors and in turn cause pain (McPartland, 2004). A persistent barrage of nociceptive signals from TrPs may eventually lead to central sensitization and the potential for neuropathic pain (p. 254). Signals may spread segmentally within the spinal cord to cause localized or referred pain (Gerwin, 2005). TrPs can also initiate viscerosomatic convergence that can generate autonomic responses such as vomiting, diarrhea, and bladder spasm.

TrPs can affect any muscle, and those involving muscles of the anterior abdominal wall, pelvic floor, and pelvic girdle can be sources of CPP. The incidence of myofascial disease is unknown, but in one study of more than 1100 women with CPP, 13 percent were diagnosed with myofascial pain syndrome (Bedaiwy, 2013). Prevalence appears to be greatest at ages between 30 and 50 years. Risk factors vary, although many TrPs can be traced to a prior specific trauma (Sharp, 2003). Accordingly, a detailed inventory of sports injuries, traumatic injuries, obstetric deliveries, surgeries, and work activities is essential.

Diagnosis

Having the patient mark painful sites on a body silhouette diagram can be an informative first step. Involvement of specific muscles will often give characteristic patterns. Patients typically describe the pain as aggravated by specific movement or activity and relieved by certain positions. Cold, damp exposure generally worsens pain. Pressure on a TrP causes discomfort and produces effects on a target area or *referral zone*. This specific and reproducible area of referral rarely coincides with dermatologic or neuronal distribution and is the feature that differentiates myofascial pain syndromes from fibromyalgia (Lavelle, 2007).

Muscle examination may be completed by flat palpation, pincer palpation, or deep palpation depending on muscle location. Flat palpation uses fingertips to roll over superficial



A B

FIGURE 12-8 Techniques for trigger point palpation. **A.** With flat palpation, fingertips stroke across the muscle surface. **B.** With pincer palpation, the muscle is grasped and palpation for trigger points is completed as the muscle slips through the fingers.

muscles, which are accessible only at the surface (Fig. 12-8). This technique is commonly used to assess the anterior abdominal wall. In muscles with greater accessibility, pincer palpation grasps the muscle belly between the thumb and fingers. With any of the palpation techniques, spot tenderness and taut muscle bands are sought. Classically, the involved muscle displays weakness and restricted stretch. TrP pressure may also elicit a local muscle twitch response, reproduce a patient's referred pain, or both.

Specific Muscle Groups

Anterior abdominal wall muscles—that is, the rectus abdominis, the obliques, and transversus abdominis muscles—may all develop TrPs. Somatovisceral pelvic symptoms from these muscles can include diarrhea or urinary frequency, urgency, or retention. Rectus abdominis muscle TrPs are frequently found along the linea semilunaris, which is the term for this muscle's lateral margin (Suleiman, 2001). Additional rectus abdominis TrPs may develop at the muscle's insertion into the pubic bone and also below the umbilicus. Within the external oblique muscle, trigger points frequently involve its lateral attachment to the anterior iliac crest. Pain usually refers to the pubic bone.

After examination of the anterior abdominal wall, muscles of the pelvis are evaluated. Following careful inspection of the external genitalia, vaginal examination proceeds slowly and cautiously with the index finger only and initially without a palpating abdominal hand. Muscles within the pelvis include the levator ani, coccygeus, obturator internus, and deep transverse perineal and piriformis muscles, and these are assessed for painful TrPs (see Fig. 12-4) (Vercellini, 2009). TrPs involving these muscles and anal sphincter muscles are frequently associated with poorly localized pain that may be described as involving the coccyx, hip, or back (Fig. 12-9). Dyspareunia is common.

Treatment

Regardless of TrP location, the treatment goal is TrP inactivation, which then allows stretching and release of taut muscle bands. Of methods, TrP point massage or more aggressive ischemic compression massage are effective (Hull, 2009). Biofeedback, relaxation techniques, or psychotherapy may be helpful adjuncts. Analgesics, antiinflammatory drugs, muscle relaxants, or neuroleptics also may be prescribed. Finally, electrical stimulation, TrP dry needling, or TrP injection may be required. In those who are unresponsive to injection of local

anesthetic agents, botulinum toxin A injection may be considered (Gyang, 2013).

Peripartum Pelvic Pain Syndrome

Also known as *pelvic girdle pain*, this condition is characterized by persistent pain that begins during pregnancy or immediately postpartum. Pain is prominent around the sacroiliac joints and symphysis and is thought to originate from injury or inflammation of the pelvic and/or lower spine ligaments. Muscle weakness, postural adjustments of pregnancy, hormonal changes, and weight of the fetus and gravid uterus are all potential contributors (Mens, 1996). Pelvic girdle pain is common. Significant pain is estimated to afflict approximately 20 percent of gravidas and 7 percent of those during the 3 months following delivery (Albert, 2002; Wu, 2004). Diagnosis is usually clinical and based on findings during specific orthopedic joint manipulation tests. These are used to recreate or provoke the pain. Treatment includes physical therapy, exercise, and analgesics typically used for CPP, described on page 261 (Vermani, 2010; Vleeming, 2008).

NEUROLOGIC ETIOLOGIES

Anterior Abdominal Wall Nerve Entrapment Syndromes

With these, anterior cutaneous branches of the intercostal nerves or branches of the ilioinguinal, iliohypogastric, genitofemoral nerves, and lateral femoral cutaneous nerves are most commonly involved (Greenbaum, 1994). These peripheral nerves can be compressed within narrow anatomic canals or rings or beneath tight ligaments, fibrous bands, or sutures. For example, each anterior cutaneous branch of an intercostal nerve traverses anteriorly through the rectus abdominis muscle. Each branch and its corresponding vessels travels through a fibrous ring found within the lateral aspect of the rectus abdominis muscle (Fig. 12-10). These branches are often seen during Pfannenstiel incision creation as the anterior rectus sheath is dissected off each rectus belly (Fig. 43-2.3, p. 934). On crossing the anterior rectus sheath, each nerve branch divides and then courses within the subcutaneous layer. Within the fibrous ring, fat surrounding the neurovascular bundle appears to pad the enclosed structures (Srinivasan, 2002). However, if this bundle receives excessive intra- or extraabdominal pressure, compression of the bundle against the fibrous ring causes nerve ischemia and pain (Applegate, 1997).

Alternatively, nerve entrapment, injury, or neuroma formation may involve branches of the ilioinguinal, iliohypogastric, lateral femoral cutaneous, or genitofemoral nerves, as described in Chapter 40 (p. 842). Involvement may follow inguinal hernia repair, low transverse abdominal incisions, and lower abdominal laparoscopic trocar placement. Hypoesthesia is the more common finding with these injuries, but pain may variably develop within months of surgery or after several years.

Criteria for diagnosing nerve entrapment are clinical and include: (1) pain aggravated by patient movement or light skin pinching over the affected area and (2) pain improvement following local anesthetic injection. In general, electromyography (EMG) is uninformative because it lacks adequate sensitivity (Knockaert, 1996). For local injection, 1- or 2-percent lidocaine and a 40-mg/mL concentration of triamcinolone can be combined in a 1:1 ratio. However, the corticosteroid may be omitted. Less than half a milliliter is injected at each pain site. Additional treatments can include oral analgesics, biofeedback, and gabapentin. If conservative options fail to bring sufficient relief, neurolysis with injection of 5- to 6-percent absolute alcohol or phenol, or surgical neurectomy may be required (Oor, 2016; Suleiman, 2001).

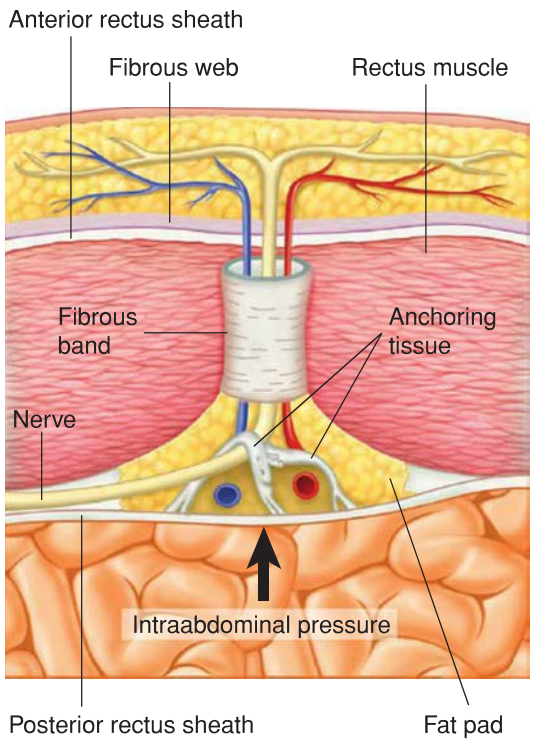

FIGURE 12-10 Nerve entrapment of the anterior cutaneous branches of one of the intercostal nerves. The nerve is compressed as it traverses the rectus abdominis muscle within a fibrous sheath.

Pudendal Neuralgia

Neuralgia is sharp, severe, shooting pain that follows the distribution of the involved nerve. Pudendal nerve entrapment may create this type of pain on the perineum. The three branches of this nerve are the perineal nerve, the inferior rectal nerve, and the dorsal nerve to the clitoris (Fig. 25-1, p. 559). Thus, pain may involve, alone or in combination, the clitoris, vulva, or rectum. Pudendal neuralgia is rare, is usually unilateral, and typically develops after age 30. In affected individuals, allodynia and hyperesthesia may be extreme to the point of disability. The pain is aggravated by sitting, is relieved by sitting on a toilet seat or standing, and may progress during the day. Pudendal neuralgia has been associated with persistent genital arousal disorder (Pink, 2014).

The diagnosis of pudendal neuralgia is clinical, and *Nantes criteria* are used by many. As inclusion criteria, pain follows the pudendal nerve innervation path, is worse with sitting, has no associated sensory loss, does not awaken patients, and is

relieved by nerve blockade (Labat, 2008). Clinical suspicion may be supported by objective testing. This may include neurophysiologic testing such as pudendal nerve motor latency and EMG, both described in Chapter 25 (p. 565). However, abnormal findings with these are not specific for pudendal neuralgia. Rarely, CT or MR imaging may be informative, although these may be performed to exclude other pathology (Khoder, 2014).

Treatment can involve physical therapy; behavioral modification; gabapentin or tricyclic antidepressants; pudendal nerve blockade, with or without corticosteroids; botulinum toxin A injection; and pudendal nerve stimulation. If these are unsuccessful, surgical nerve decompression may be elected.

Piriformis Syndrome

Compression of the sciatic nerve by the piriformis muscle may lead to buttock or low back pain in the distribution of the sciatic nerve (Broadhurst, 2004). This is termed the *piriformis syndrome.* Proposed mechanisms for compression include: contracture or spasm of the piriformis muscle from trauma, overuse and muscle hypertrophy, and congenital variations, in which the sciatic nerve or its divisions pass directly through this muscle (Hopayian, 2010).

Fishman and associates (2002) estimate the piriformis syndrome to be responsible for 6 to 8 percent of cases of low back pain and sciatica in the United States each year. Symptoms include pain and tenderness involving the buttocks, with or without radiation into the posterior thigh, and external tenderness near the greater sciatic notch. Pain is worse with activity, prolonged sitting, walking, and internal rotation of the hip (Hopayian, 2018; Kirschner, 2009). Dyspareunia has a common but variable association and has been demonstrated in 13 to 100 percent of cases (Hopayian, 2010).

Diagnosis of the syndrome is clinical and based on findings during specific orthopedic joint manipulation tests (Michel, 2013). Nerve conduction and EMG are typically nondiagnostic. MR imaging may be helpful by identifying a swollen or enlarged piriformis muscle or anatomic muscle variants (Vassalou, 2018). Treatment is conservative and includes physical therapy, NSAIDs, muscle relaxants, or neuropathic pain agents such as gabapentin, nortriptyline, or carbamazepine. Therapeutic injections of local anesthetics, with or without corticosteroids, or of botulinum toxin A may be used. Surgery is reserved for refractory cases.

Breast disease in women encompasses a spectrum of benign and malignant disorders, which present most commonly as breast pain, nipple discharge, or palpable mass. The specific causes of these symptoms vary with patient age. Benign disorders predominate in young premenopausal women, whereas malignancy rates rise with advancing age. Evaluation of breast disorders usually requires the combination of a careful history, physical examination, imaging, and, when indicated, biopsy.

ANATOMY

Ductal System

The glandular portion of the breast is composed of 12 to 15 independent ductal systems that each drains approximately 40 lobules (Fig. 13-1). Each lobule consists of 10 to 100 milk-producing acini that empty into small terminal ducts (Fig. 13-2) (Parks, 1959). Histologically, acini and terminal ducts are lined by a cuboidal epithelium and an outer layer of myoepithelial cells. Terminal ducts drain into larger collecting ducts that merge into even larger ducts, which exhibit a saccular dilation just below the nipple called a *lactiferous sinus*.

In general, only six to eight openings are visible on the nipple surface. These drain the dominant ductal systems, which account for approximately 80 percent of the breast's glandular volume (Going, 2004). Minor ducts either terminate just below the nipple surface or open on the areola near the base of the nipple. The areola itself contains numerous lubricating sebaceous glands, called *Montgomery glands*, which are often visible as punctate prominences.

In addition to epithelial structures, the breast is composed of varying proportions of collagenous stroma and fat. The distribution and abundance of these stromal components accounts for a breast's consistency when palpated and for its imaging characteristics.

Lymphatic Drainage

Afferent lymphatic drainage of the breast is provided by dermal, subdermal, interlobar, and prepectoral systems (Fig. 13-3) (Grant, 1953). Each of these may be viewed as a lattice of valveless channels that interconnect with every other system and that ultimately drain into one or two axillary lymph nodes (the sentinel nodes). Because all of these systems are interconnected, the breast drains as a unit, and injection of colloidal dyes in any part of the breast at any level will result in accumulation of dye in the same one or two axillary sentinel lymph nodes. The axillary lymph nodes receive most of the lymphatic drainage of the breast and consequently are the nodes most frequently involved with breast cancer metastases (Hultborn, 1955). However, there are also alternate drainage pathways that do not appear to interconnect with other networks and that drain directly into internal mammary, supraclavicular, contralateral axillary, or abdominal lymph node basins.

DEVELOPMENT AND PHYSIOLOGY

During fetal development, the primordial breast arises from the basal layer of the epidermis. Before puberty, the breast is a rudimentary bud composed of a few branching ducts capped with alveolar buds, end buds, or small lobules (Osin, 1998). At puberty, usually between the ages of 10 and 13 years, ovarian estrogen and progesterone cooperate to direct organized communication between breast epithelial cells and mesenchymal cells, resulting in extensive branching of the ductal system and development of lobules (Ismail, 2003). Specific disorders of this

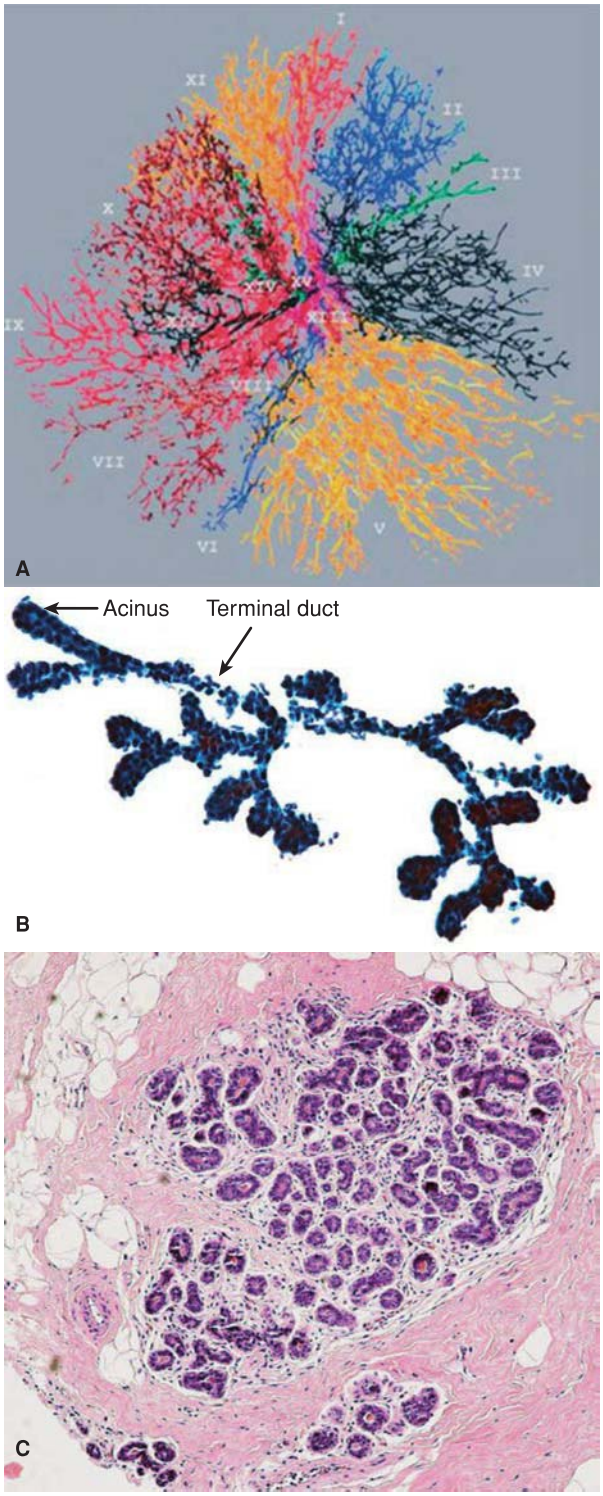

FIGURE 13-1 **A.** Ductal anatomy of the breast. (From Going, 2004, with permission.) **B.** Terminal duct—acinar structure from a fine-needle aspiration biopsy. **C.** Histology of a normal breast lobule. The terminal duct lobular units are surrounded by loosely cellular intralobular stroma, which consists of dense fibrous tissue admixed with adipocytes.

development are discussed in Chapter 15 (p. 328). Final differentiation of the breast is mediated by progesterone and prolactin and is not completed until the first full-term pregnancy (Grimm, 2002; Ismail, 2003).

During the reproductive years, terminal ducts near the acini and the acini themselves are most sensitive to ovarian hormones and prolactin. Most forms of benign and malignant breast disease arise in these terminal duct–acinar structures. Breast epithelial cells proliferate during the luteal phase of the menstrual cycle when estrogen and progesterone levels are elevated, and then undergo programmed cell death at the end of the luteal phase, when these hormone levels decline (Anderson, 1982; Soderqvist, 1997). This effect is mediated by paracrine signaling induced by estrogen receptor activation and is associated with greater water content in the extracellular matrix (Stoeckelhuber, 2002). This is often recognized as breast fullness and tenderness in the week preceding menses.

At menopause, when ovarian estrogen production ceases, breast lobules involute, and the collagenous stroma is replaced by fat. Estrogen receptor expression is negatively regulated by estrogen, and thus estrogen receptor expression rises after menopause (Khan, 1997). Despite a decline in ovarian estrogen production, postmenopausal women continue to produce estrogen through the action of the enzyme aromatase, which converts adrenal androgens to estrogen (Bulun, 1994). Aromatase is found in fat, muscle, and breast tissue.

EVALUATION OF A BREAST LUMP

It is not possible to distinguish benign from malignant or cystic from solid breast masses by clinical examination. However, findings from clinical examination, interpreted in conjunction with imaging and pathology (the triple test), contribute significantly to management decisions (Hermansen, 1987).

Physical Examination

The breast is comma shaped, and the comma's tail corresponds to the axillary tail of Spence. This extension can be large, especially during pregnancy and lactation, and is frequently mistaken for an axillary mass.

Clinical examination of the breast begins with inspection of the breast for dimpling, nipple retraction, or skin changes. This examination is fully described in Chapter 1 (p. 2). The presence and character of expressible nipple discharge is recorded. In addition, the location of a mass is specifically documented according to its clock position and then measured along its long axis using a ruler or caliper (Fig. 13-4). The distance from the center of the nipple to the center of the mass is specified. Since numerous health care providers are typically involved in the evaluation and management of the same breast mass, the most useful entry in the clinical record will define the location and size of the mass (e.g., right breast, 2-cm mass, 3:00, 4 cm from the nipple). Clinical examination alone can never exclude malignancy. However, noting that a mass has benign features such as smoothness, roundness, and mobility will factor into the ultimate decision to excise or observe a lesion. Evaluation also includes careful examination of the axillae, infraclavicular fossa, and supraclavicular fossa to identify lymphadenopathy.

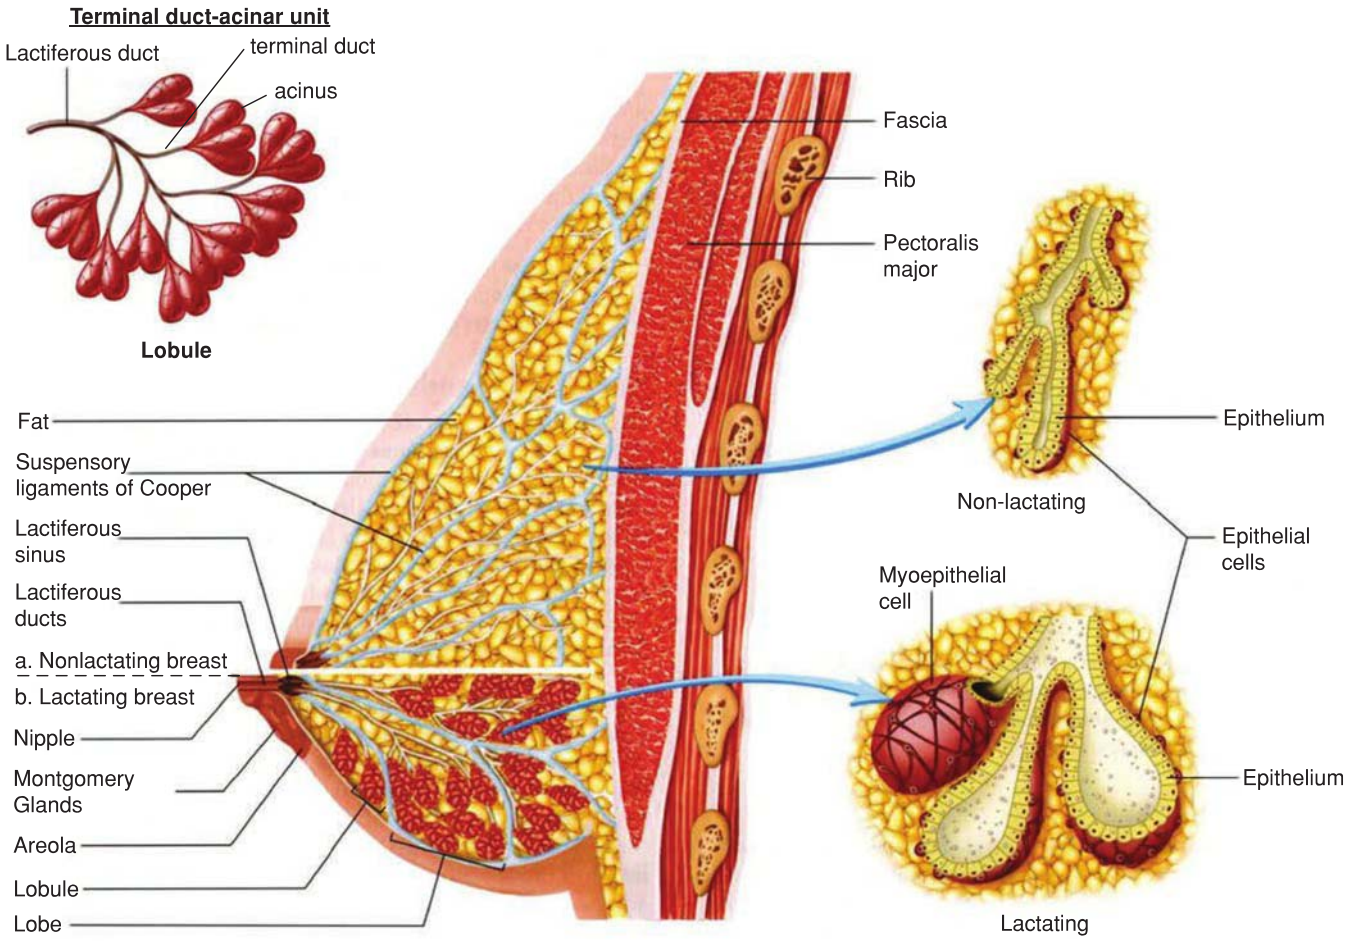

FIGURE 13-2 Breast anatomy. (From Seeley, 2006, with permission.)

Diagnostic Imaging

Imaging of a suspected mass may begin with mammography that includes magnification, extra compression, or extra views beyond the usual medial lateral oblique and cranial caudal views that are typically used for screening. Unlike screening mammography, diagnostic mammography may be appropriate for women of any age. However, because of their radiosensitive breast tissue, mammography is generally avoided in women younger than 25 years, for whom magnetic resonance (MR) imaging is a suitable option. In addition, sonography is invaluable for determining whether a mass is cystic or solid and is a component of most diagnostic imaging algorithms. Certain features of solid masses, such

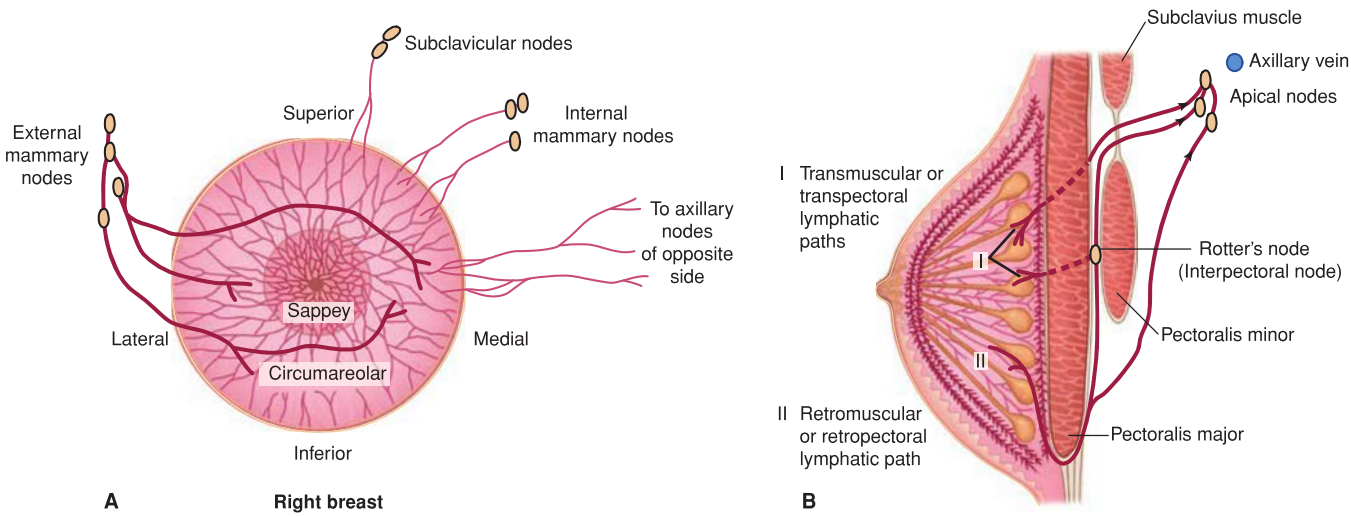

FIGURE 13-3 Lymphatic drainage of the breast. **A.** Accessory drainage pathways. **B.** Classic axillary drainage pathways. (Redrawn from Grant, 1953, with permission.)

as irregular margins, internal echoes, or a width-to-height ratio <1.7 may suggest malignancy (Stavros, 1995).

Diagnostic imaging results are summarized according to the Breast Imaging Reporting and Data System (BI-RADS) classification (Table 13-1) (D'Orsi, 2013). Lesions that are graded BI-RADS 5 are highly suggestive of malignancy, and ≥95 percent of these are ultimately proven to be cancerous. Decreasing numerical grades are associated with diminishing probability of malignancy.

Breast Biopsy

Evaluation of a solid breast mass is completed by needle biopsy. These biopsies should be performed after an imaging test or a minimum of 2 weeks prior to an imaging test. This is because resulting tissue trauma can produce image artifacts that simulate malignancy (Sickles, 1983). Options include fine-needle aspiration (FNA) biopsy or core needle biopsy. The trend in recent years favors core needle biopsy (Tabbara, 2000). Although FNA takes less time to perform and is less expensive than core needle biopsy, it is less likely to provide a specific diagnosis and has a higher insufficient sample rate (Shannon, 2001). FNA retrieves clusters of epithelial cells that may be interpreted as benign or malignant, but it cannot reliably differentiate between benign proliferative lesions and fibroepithelial neoplasms or between ductal carcinoma in situ and invasive cancer (Boerner, 1999; Ringberg, 2001).

In contrast, core needle biopsy is performed using an automated device that takes one core at a time or is completed using a vacuum-assisted device that, once initially positioned, delivers multiple cores. Needle biopsy of solid masses should be done prior to excision, as the biopsy results contribute significantly to surgical planning (Cox, 1995).

Triple Test

The combination of clinical examination, imaging, and needle biopsy is called the *triple test* (Wai, 2013). When all three assessments suggest a benign lesion or all three suggest a breast cancer, the triple test is said to be concordant. A concordant benign triple test is >99-percent accurate, and breast lumps in this category can be followed by clinical examination alone at 6-month intervals. If any of the three assessments suggests malignancy, the lump should be excised regardless of results from the other two. It is always appropriate to offer excision of a fully evaluated breast lump, even after a benign concordant triple test result, as breast lumps can be a source of significant anxiety.

BENIGN LUMPS AND FIBROEPITHELIAL NEOPLASMS

Cysts

Most breast cysts arise from apocrine metaplasia of lobular acini. They are generally lined by a single layer of epithelium

TABLE 13-1. Breast Imaging Reporting and Data System (BI-RADS)

BI-RADS Category	Description	Examples
0	Additional views or sonography required	Focal asymmetry, microcalcifications, or a mass identified on a screening mammogram
1	No abnormalities identified	Normal fat and fibroglandular tissue
2	Not entirely normal, but definitely benign	Fat necrosis from a prior excision, stable biopsy-proven fibroadenoma, stable cyst
3	Probably benign	Circumscribed mass that has been followed for <2 years
4A	Low suspicion for malignancy, but intervention required	Probable fibroadenoma, complicated cyst
4B	Intermediate suspicion for malignancy, intervention required	Partially indistinctly marginated mass otherwise consistent with a fibroadenoma
4C	Moderate suspicion, but not classic for carcinoma	New cluster of fine pleomorphic calcifications, ill-defined irregular solid mass
5	Almost certainly malignant	Spiculated mass, fine linear and branching calcifications
6	Biopsy-proven carcinoma	Biopsy-proven carcinoma

that ranges from flattened to columnar. One autopsy series that included 725 women reported microcysts in 58 percent and cysts >1 cm in 21 percent (Davies, 1964). The incidence of breast cysts peaks between 40 and 50 years, and the lifetime incidence of palpable breast cysts is estimated to be 7 percent (Haagensen, 1986).

Breast cysts are diagnosed and classified by sonography. The three types of cysts are simple, complicated, and complex (Berg, 2003). Simple cysts are sonolucent, have a smooth margin, and show enhanced through-transmission (Fig. 13-5). These lesions do not require special management or monitoring, but they may be aspirated if painful. Recurrent cysts can be reimaged and reaspirated, but recurrent symptomatic cysts are best managed by excision.

Complicated cysts show internal echoes during sonography and can sometimes be indistinguishable from solid masses. Internal echoes are usually caused by proteinaceous debris. Consideration is given to aspirating complicated cysts. The aspirated material may be submitted for culture, if it is purulent, or for cytology, if worrisome clinical or imaging features are found. If the sonographic abnormality does not resolve completely with aspiration, a core-needle biopsy is usually performed.

Complex cysts show septa or intracystic masses during sonographic evaluation. An intracystic mass usually represents a papilloma, but medullary carcinoma, papillary carcinoma, and some infiltrating ductal carcinomas can present as complex cysts. Although some advocate core needle biopsy for the evaluation of complex cysts, this procedure can decompress a cyst, making it difficult to localize at the time of surgery. Additionally, papillary lesions diagnosed by needle biopsy will require excision. Thus, it seems reasonable to recommend excision of all complex cysts.

Fibroadenoma

This is best considered a focal developmental abnormality of a terminal duct-lobular unit and not a true neoplasm. Histologically, fibroadenomas are composed of glandular and cystic epithelial structures surrounded by a cellular stroma. Fibroadenomas account for 7 to 13 percent of breast clinic visits and had a prevalence of 9 percent in one autopsy series (Dent, 1988; Franyz, 1951). They often present in adolescence, are recognized most frequently in premenopausal women, and usually spontaneously involute at menopause.

Fibroadenomas classified as benign concordant by the triple test can be safely followed without excision. Because some fibroadenomas may grow large, and because benign phyllodes tumors are often indistinguishable from fibroadenomas by imaging and needle biopsy, a fibroadenoma that is growing should be excised.

For most women with fibroadenomas, the risk of cancer is not increased. Exceptions are cases of complex fibroadenomas, fibroadenomas adjacent to another proliferative lesion, or those in women with a significant family breast cancer history (Greenberg, 1998).

Phyllodes Tumors

These are true biphasic neoplasms characterized by epithelial-lined spaces surrounded by cellular stroma. Both the epithelial

and stromal components can be monoclonal and clonally related (Karim, 2013). Phyllodes tumors are classified as benign, borderline, or malignant, based on the degree of stromal cell atypia, number of mitoses, tumor margin characteristics, and abundance of stromal cells (Oberman, 1965). Phyllodes tumors account for less than 1 percent of breast neoplasms, and the median age at diagnosis is 40 years (Kim, 2013; Reinfuss, 1996). Malignant phyllodes tumors can metastasize to distant organs, with lung being the primary site. Chest radiographs or chest computed tomography (CT) scanning are appropriate staging tests for malignant cases. Phyllodes tumors rarely metastasize to lymph nodes, thus axillary staging is not required unless nodes clinically appear involved (Chaney, 2000).

Previously, treatment consisted of wide local excision with a minimum 1-cm margin, regardless of phyllodes grade. For benign phyllodes, data now show that excision with a negative or a 1-mm margin may be sufficient (Shaaban, 2017; Tremblay-LeMay, 2017). Positive margins warrant close observation but do not necessarily require reexcision (Moo, 2017). Wide excision with a 1-cm margin is still advised for borderline and malignant phyllodes.

Mastectomy may be required to achieve this margin, as the median tumor size at presentation is 5 cm. Local recurrence rates for completely excised tumors range from 8 percent for benign lesions to 36 percent for malignant ones. Distant metastases develop in <1 percent of benign phyllodes cases but in up to 17 percent of malignant ones (Tan 2016). Postoperative adjuvant radiation therapy may be indicated for high-risk cases (Barth, 2009).

NIPPLE DISCHARGE

Fluid can be expressed from the nipple ducts of at least 40 percent of premenopausal women, 55 percent of parous women, and 74 percent of women who have lactated within 2 years (Wrensch, 1990). The fluid generally issues from more than one duct and may range from milky white to dark green or brown. The green color is related to the content of cholesterol diepoxides and does not suggest underlying infection or malignancy (Petrakis, 1988).

Multiduct discharges that are elicited only following manual expression are considered physiologic and do not require additional evaluation. However, spontaneous discharges merit evaluation (Fig. 13-6). Spontaneous milky nipple discharge, also

called galactorrhea, results from various causes (Table 13-2) (Chap. 16, p. 360). Of these, pregnancy is a frequent cause of new-onset spontaneous discharge, and a bloody multiduct discharge during pregnancy is not uncommon.

Pathologic nipple discharge is defined as a spontaneous single-duct discharge that is serous or bloody. The rate of underlying malignancy ranges from approximately 2 percent for young women with no associated clinical or imaging findings to 20 percent for older women with associated findings (Cabioglu, 2003; Lau, 2005). Most pathologic nipple discharges are caused by benign intraductal papillomas, which are simple milk duct polyps (Urban, 1978). They arise in the major milk ducts, generally within 2 cm of the nipple, and contain a velvety papillary epithelium on a central fibrovascular stalk.

Evaluation of a pathologic nipple discharge begins with breast examination. Careful evaluation can frequently locate a trigger point on the areolar edge that elicits the discharge when pressed. Occult-blood testing and microscopic examination of the discharge can provide additional information. A glass slide that has been touched to the discharge and immediately fixed in 95-percent alcohol may be used for cytologic assessment. Nipple fluid samples are acellular in 25 percent of cases and thus cannot exclude an underlying malignancy (Papanicolaou, 1958). However, malignant cells, if found, are highly correlated with an underlying cancer (Gupta, 2004).

Following these examinations, diagnostic mammography and an assessment of the subareolar ducts by sonography or ductography are indicated. Diagnostic mammography is usually negative, but it may occasionally identify an underlying ductal carcinoma in situ. Mammary ductography, also known as *galactography*, requires cannulating the affected duct, injecting radiocontrast, and then performing mammography (Fig. 13-7).

An evaluation of the subareolar ducts, as described above, is required to localize an intraductal lesion for subsequent excision. However, pathologic nipple discharge is *definitively* diagnosed and treated by subareolar duct excision, which is also known as *microductectomy* (Locker, 1988). Subareolar duct excision can also be used to treat bothersome multiduct discharges not associated with prolactinoma.

BREAST INFECTIONS

Puerperal Infections

Breast infections are generally divided into puerperal, which develop during pregnancy and lactation, and nonpuerperal. Of these, pregnancy-related breast infection is characterized by warm, tender, diffuse breast erythema and is associated with systemic signs of infection such as fever, malaise, and leukocytosis. The most common organism is staphylococcal, and it is successfully treated with oral or intravenous antibiotics, depending on clinical severity. However, infection may also progress to form deep parenchymal abscesses (Branch-Elliman, 2012). Sonographic examination is highly sensitive for identifying underlying abscesses if mastitis does not improve rapidly with antibiotics or if an abscess is suggested clinically (Fig. 13-8). Women with puerperal mastitis ideally continue to breastfeed or breast pump during treatment to prevent milk stasis, which may contribute to infection progression (Thomsen, 1983). Cracked or excoriated nipples may provide entry for bacteria and are treated with lanolin-based lotions or ointments.

Appropriate antibiotics for puerperal mastitis include those covering staphylococcal species, although group A and B *Streptococcus*, *Corynebacterium*, and *Bacteroides* species and *Escherichia coli* are less frequently isolated. Commonly, cephalexin (Keflex) or dicloxacillin (Dynapen), each given at dosages of 500 mg orally four times daily, or the combination of amoxicillin and clavulanate (Augmentin), 500 mg orally three times daily, may be prescribed for 7 days. Erythromycin, 500 mg orally four times daily, will provide adequate coverage for those with a penicillin allergy. Methicillin-resistant *Staphylococcus aureus (MRSA)* is becoming a more prevalent community-acquired pathogen causing mastitis in pregnancy and the puerperium (Laibl, 2005; Stafford, 2008). If MRSA is suspected or if a patient fails to improve on an initial regimen, then trimethoprim-sulfamethoxazole double strength (Bactrim DS, Septra DS), one or two tablets orally twice daily, or clindamycin, 300 mg orally three times daily, is a suitable choice. In ill patients with extensive infection, hospitalization and intravenous antibiotics are typically required. In these complicated cases, MRSA coverage may be prudent, and clindamycin, 600 mg IV every 8 hours, or vancomycin, 1 g IV every 12 hours, can be administered. Intravenous antibiotics are typically given until the woman is afebrile for 24 to 48 hours. Oral antibiotics are then continued to complete a 7- to 10-day course.

An abscess that is initially present or that develops is drained. For smaller abscesses, sonographically guided needle aspiration using local analgesia has evidence-based support in small studies (Eryilmaz, 2005; Kang, 2016; Naeem, 2012). Incision and drainage may be needed for large abscesses or those failing to resolve with aspiration.

Focal mastitis may result from an infected galactocele. A tender mass will usually be palpable at the site of skin erythema. Needle aspiration of the galactocele and antibiotics are frequently all that is required, but recurrence or progression may mandate surgical drainage.

Nonpuerperal Infections

Uncomplicated cellulitis in a nonirradiated breast and in a nonpuerperal setting is uncommon. Accordingly, its presence prompts imaging and biopsies to exclude inflammatory breast cancer, described on page 296.

Nonpuerperal breast abscesses are generally classified as peripheral or subareolar. Peripheral abscesses usually are skin infections such as folliculitis or infection of epidermal inclusion cysts or Montgomery glands. These abscesses are all adequately treated by surgical drainage and then antibiotics discussed in the previous section. In contrast, subareolar abscesses arise from keratin-plugged milk ducts directly behind the nipple. The abscess itself usually presents under the areola, and fistulous communications between multiple abscesses are common (Kasales, 2014). Simple drainage is associated with a recurrence rate of nearly 40 percent, thus effective treatment requires subareolar duct excision and complete removal of sinus tracts. In general, surgical drainage of nonpuerperal breast abscesses is usually always accompanied by biopsy of the abscess wall, as breast cancer occasionally presents as an abscess (Benson, 1989; Watt-Boolsen, 1987).

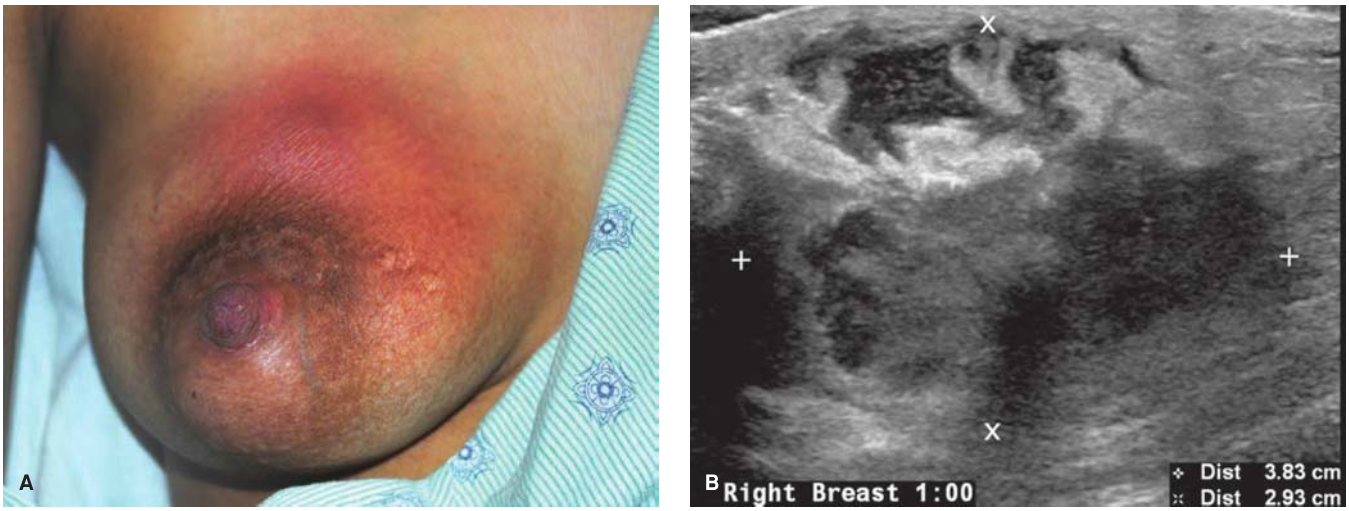

FIGURE 13-8 A. Puerperal right breast abscess. **B.** Breast sonogram displays the hypoechoic abscess contents, and calipers mark its borders. (Reproduced with permission from Dr. Agnieszka Dombrowska.)

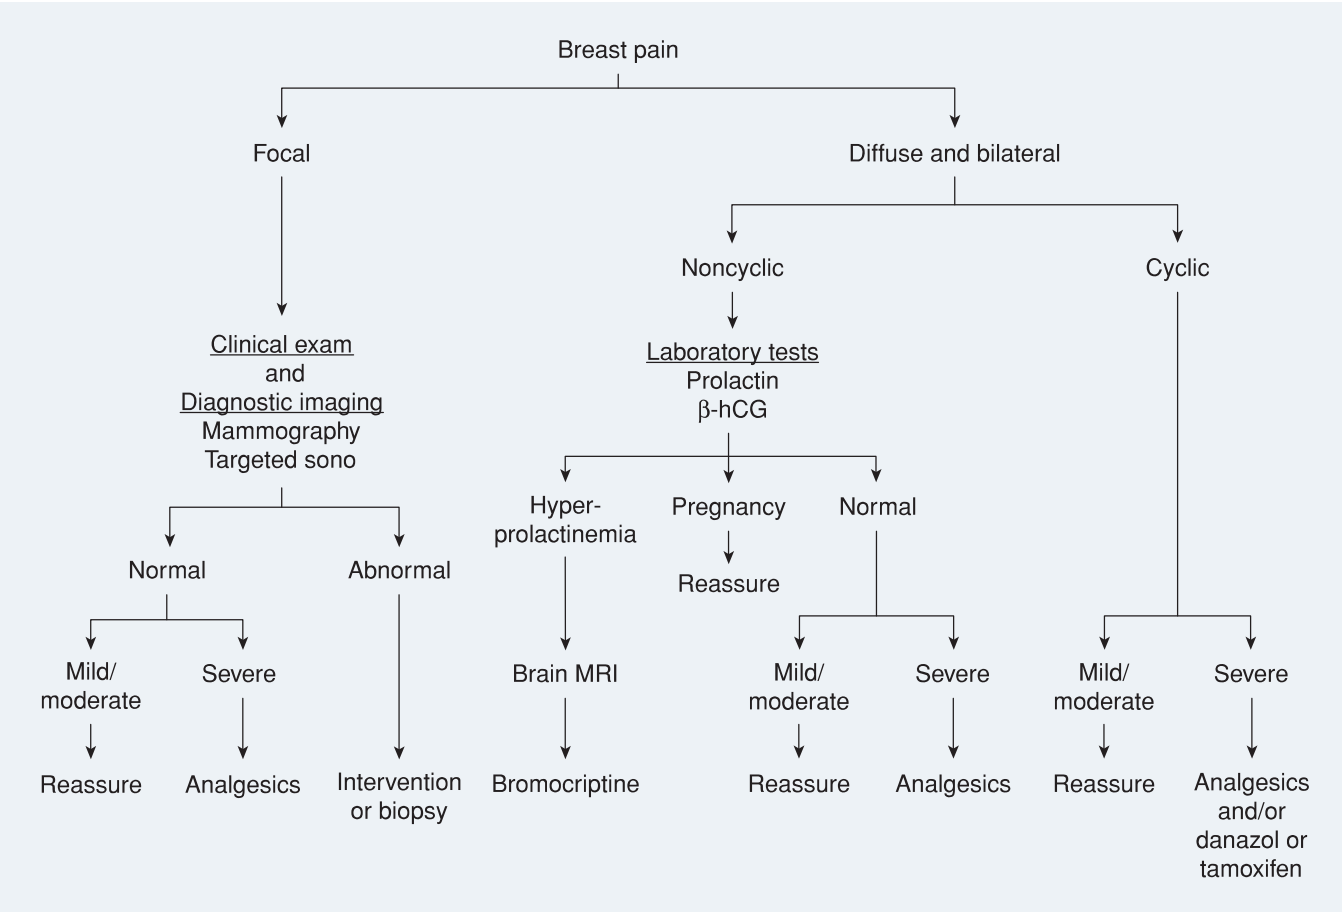

FIGURE 13-9 Diagnostic algorithm to evaluate mastalgia. Oil of evening primrose or vitamin E is frequently used for mild/moderate pain, but the effects are no better than placebo. hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging.

Idiopathic granulomatous mastitis (IGM) is not a true infection. It is included in this section because the painful masses, fluid collections, skin erythema, ulceration, and draining sinus tracts are often confused with infection. Core needle biopsy will show noncaseating granulomas, and fluid aspirated from apparent "abscesses" is nearly always sterile. Tissue stains can be used to exclude tuberculosis or mycotic infection. Wegener granulomatosis and sarcoidosis are considered in the initial differential diagnosis. This is a self-limiting condition that may take years to resolve. Procedures should be minimized as they will often result in painful draining sinuses. High-dose corticosteroids or methotrexate have been used for treatment, but their efficacy is unclear (Mohammed, 2013; Pandey, 2014).

MASTALGIA

The prevalence of breast pain is 66 percent and is higher for women nearing menopause than for younger women (Euhus, 1997; Maddox, 1989). The precise etiology of mastalgia is unknown. Estrogen- and progesterone-mediated changes in interstitial water content and thus in interstitial pressure are implicated.

Mastalgia is generally classified as cyclic or noncyclic. Noncyclic mastalgia is often focal and shows no relationship to the menstrual cycle. Although focal mastalgia is frequently caused by a simple cyst, breast cancer occasionally presents as focal breast pain. Therefore, this complaint is evaluated by careful clinical examination, targeted imaging, and needle biopsy of any palpable or imaging abnormalities.

In contrast, cyclic mastalgia is usually bilateral, diffuse, and most severe during the late luteal phase of the menstrual cycle (Gateley, 1990). It remits with the onset of menstruation. Cyclic mastalgia requires no specific evaluation and is generally managed symptomatically with nonsteroidal antiinflammatory agents (Fig. 13-9). Various other proposed treatments include bromocriptine, vitamin E, or oil of evening primrose. However, outcomes are no better than placebo in the best randomized clinical trials, except for bromocriptine in the subset of women with elevated prolactin levels (Kumar, 1989; Mansel, 1990). For the most severe cases, several agents are effective when administered during the last 2 weeks of the menstrual cycle. These include: (1) danazol, 200 mg orally daily; (2) the selective estrogen-receptor modifier toremifene (Fareston), 20 mg orally daily; or (3) tamoxifen (Nolvadex), 20 mg orally daily. Pregnancy must first be excluded and then avoided if these medications are used.

BENIGN BREAST DISEASE

Benign Breast Disease without Atypia

The primary tissue components of the breast are fat, fibrous stroma, and epithelial structures. The hormonally responsive

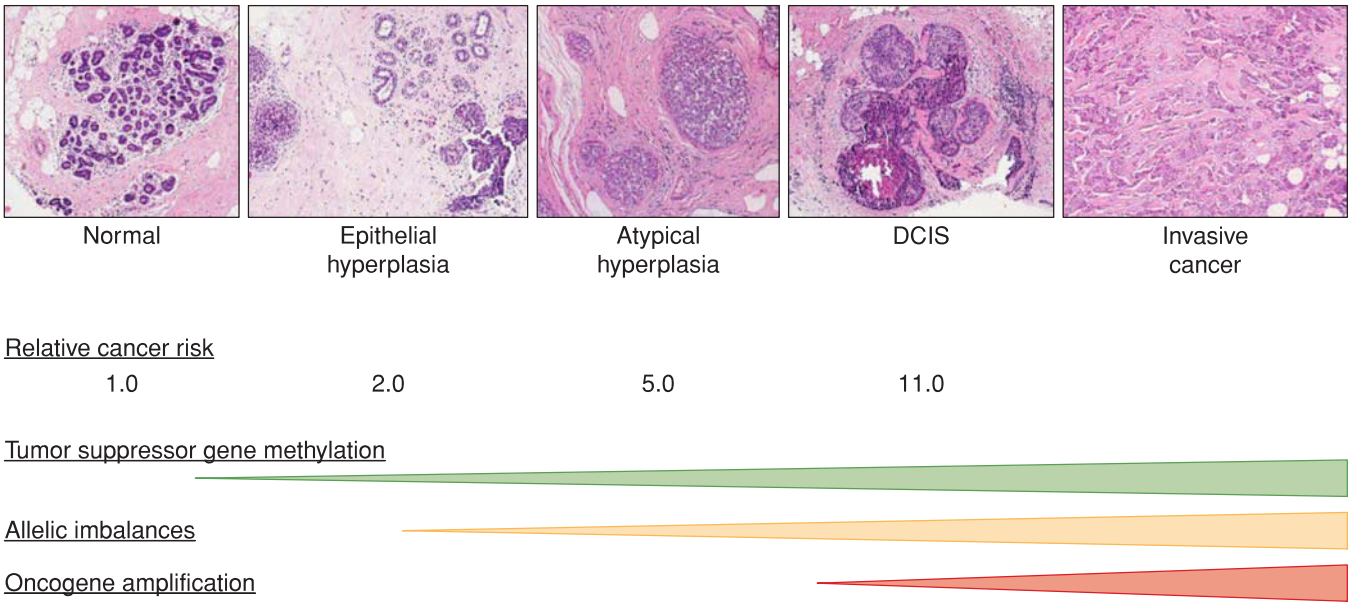

FIGURE 13-10 Histologic progression from normal breast tissue to cancer. DCIS = ductal carcinoma in situ.

component is the epithelium, but considerable paracrine communication exists between the epithelium and stroma. The natural hormonal changes of puberty, pregnancy, lactation, and menopause drive considerable physiologic remodeling of breast tissue during a woman's lifetime, but pathologic remodeling is observed in some. This is initially characterized by acinar dilation and fibrosis, termed *nonproliferative benign breast disease*. Depending on the extent and pattern of these changes, a breast may appear mammographically dense, feel nodular to palpation, or both. The term "fibrocystic change" is often used to refer to palpably nodular breast tissue or to the histologic pattern of dilated ducts and acini invested with dense collagenous stroma. This is not a significant breast cancer risk factor and does not require any special management.

When this change is accompanied by accumulation of luminal epithelial cells (e.g., epithelial hyperplasia), it is called *benign proliferative disease* (Fig. 13-10). This change has been linked to higher levels of estrogen, insulin, and certain inflammatory cytokines and to reduced levels of the beneficial adipokine adiponectin (Catsburg, 2014). Benign proliferative breast disease without atypia is a modest breast cancer risk factor, with a relative risk of 1.5 to 1.9 (Dupont, 1993; Hartmann, 2005; Sneige, 2002).

Benign Proliferative Disease with Atypia

Atypia refers to specific alterations in the size, shape, or nuclear features of individual epithelial cells in combination with the way groups of cells are organized. Atypical proliferation of ductal cells is termed atypical ductal hyperplasia (ADH), whereas similar changes in acinar cells are termed atypical lobular hyperplasia (ALH). As more and more terminal ducts or acini become involved, the condition is recognized as ductal carcinoma in situ (DCIS) or lobular carcinoma in situ (LCIS), respectively, which are discussed in later sections (Ringberg, 2001).

Benign proliferative disease with atypia historically accounts for 4 percent of benign breast lesions (Hartmann, 2005). However, the incidence has declined coincident to reductions in hormone replacement therapy use (Menes, 2009).

Importantly, the difference between ADH and low-grade DCIS is based on the area occupied by the proliferative epithelial cells (Vandenbussche, 2013). Accordingly, surgical excision is usually recommended when ADH is diagnosed by core needle biopsy, as 4 to 38 percent of cases will be upgraded to in situ or invasive cancer. However, for ALH or LCIS diagnosed in core needle biopsy samples, excision is no longer recommended when imaging is not suspicious (Bevers, 2018).

Chemoprevention is an excellent option for high-risk women with atypical hyperplasia. These lesions are estrogen-driven, and tamoxifen reduces breast cancer risk by 52 to 86 percent for these women (Coopey, 2012; Fisher, 1999).

Benign proliferative disease with atypia is a marker of increased breast cancer risk. Relative risks are 4.5 to 5.0, and absolute risks approximate 1 percent per year for 20 to 30 years (Degnim, 2007; Dupont, 1993). This risk is higher for more extensive lesions. Risk does not appear to rise further with hormone replacement use.

LOBULAR CARCINOMA IN SITU

Similar to proliferative ductal lesion, LCIS differs from ALH by the greater extent of lobular cell proliferation with LCIS and increased acini distention. Two main types of LCIS are classic and pleomorphic. Classic LCIS is not associated with specific mammographic or palpable features and thus is only diagnosed incidentally. Classic LCIS has not traditionally been viewed as a direct precursor of breast cancer, but this view is changing. For example, although LCIS is associated with greater cancer risk for both breasts, women with LCIS most commonly develop carcinoma in the ipsilateral breast (Fisher, 2004b; Ottesen, 1993; Salvadori, 1991). Moreover, infiltrating lobular cancers frequently show associated LCIS, and a clonal relationship

between LCIS and subsequent invasive cancer has been demonstrated (Abner, 2000; Andrade, 2012; Sasson, 2001).

With LCIS, the risk for developing breast cancer averages 1 percent per year. This can be modified upward by early age at diagnosis, family history of breast cancer, and extensive disease (Bodian, 1996). Classic LCIS is strongly estrogen receptor–positive, and tamoxifen reduces breast cancer risk by 56 percent in this setting (Fisher, 1999).

Pleomorphic lobular carcinoma in situ (P-LCIS) is thought to be more aggressive than classic LCIS. P-LCIS may be diagnosed as a palpable mass or on mammogram as fine pleomorphic calcifications or architectural distortion (Jorns, 2014; Savage, 2018). P-LCIS is a relatively new diagnosis, and there is no clear consensus on its treatment (Wazir, 2016).

When P-LCIS is diagnosed from a core needle biopsy sample, the final pathologic diagnosis will be upgraded to either DCIS or invasive cancer in 30 to 40 percent of cases (Fasola, 2018; Masannat, 2018). The more aggressive character of P-LCIS suggests that it may best be approached in a manner similar to DCIS (Masannat, 2018). Unlike the classic form of LCIS, P-LCIS should be considered for complete excision with negative margins (National Comprehensive Cancer Network, 2018). Occasionally P-LCIS is also treated with adjuvant radiotherapy. However, data are limited, and more evidence is needed.

The Ki67 index, a protein marker of cell proliferation, is often higher in pleomorphic LCIS than in classic LCIS. Similarly, Her-2/neu, a protein receptor associated with cancer proliferation, is more commonly amplified in P-LCIS. In contrast, estrogen and progesterone receptor expression is lower in P-LCIS than in classic LCIS (Chen, 2009). Although tamoxifen is an effective chemopreventive agent in classic LCIS, its efficacy for P-LCIS is unclear.

DUCTAL CARCINOMA IN SITU

DCIS can be understood as a condition in which cancer cells fill portions of a mammary ductal system without invading beyond the duct's basement membrane (Fig. 13-11) (Ringberg, 2001). Although DCIS cells have accumulated many of the DNA changes common to invasive breast cancer, they lack certain critical changes that would permit them to persist outside of the duct (Aubele, 2002). DCIS is currently classified as stage 0 breast cancer.

The U.S. incidence of DCIS has risen and plateaued in parallel with that of invasive breast cancer. DCIS currently accounts for 25 to 30 percent of all breast cancers in the United States. It is most commonly diagnosed by screening mammography as it is frequently associated with pleomorphic, linear, or branching calcifications (Fig. 13-12).

Although considered stage 0 breast cancer, DCIS's classification as a carcinoma has spurred considerable debate. Namely, the chance of dying of breast cancer after a DCIS diagnosis is 3.3 percent at 20 years, and this is not reduced by mastectomy compared with breast-conserving therapy (Fig. 13-13) (Narod, 2015; Solin, 1996). The reason to treat DCIS is to reduce future invasive cancer risk. However, most DCIS lesions do not progress to invasive cancer, even if undertreated. Several clinical trials are currently evaluating observation with or without endocrine therapy as a management strategy.

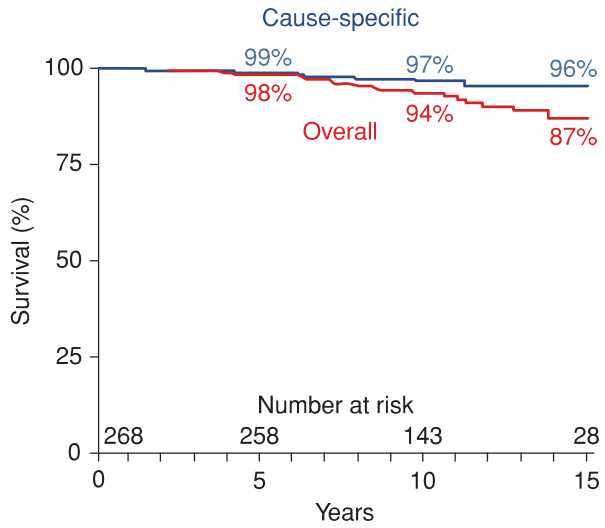

FIGURE 13-13 Cause-specific and overall survival rates for ductal carcinoma in situ. (From Solin, 1996, with permission.)

Current guidelines recommend excision of DCIS with at least a 2-mm margin (Morrow, 2016). This may require mastectomy if DCIS is extensive or if there are other contraindications to breast conservation. When breast conservation is possible, postoperative breast irradiation will reduce the local recurrence rate by 50 percent (Fisher, 1993). Current interests are focused on recognizing which patients will or will not benefit from radiotherapy. Early age at diagnosis and palpable DCIS consistently predict greater recurrence risk and favor adjunctive radiation. Molecular assays for predicting this benefit are available commercially.

Axillary staging is generally not included in the management of DCIS. Some have advocated sentinel lymph node (SLN) biopsy for large, high-grade DCIS diagnosed by needle biopsy and treated by lumpectomy, as occult invasive cancer is diagnosed in 10 percent of these cases (Wilkie, 2005). SLN biopsy in conjunction with mastectomy is less controversial, as it is not possible to go back and perform SLN biopsy if an occult invasive cancer is diagnosed in this setting.

Adjuvant endocrine therapy (tamoxifen or aromatase inhibitor) is recommended for estrogen receptor–positive DCIS treated by breast conservation (Fisher, 1999). This is not associated with a statistically significant improvement in overall survival rates. However, it does significantly reduce the incidence of ipsilateral invasive cancer and also reduces the risk of contralateral breast cancer.

Paget Disease of the Nipple

This type of DCIS presents as a focal eczematous rash of the nipple (Fig. 13-14). Ductal carcinoma cells, responding to chemoattractants secreted by cells in the dermis, migrate to the surface of the nipple, inducing skin breakdown (Schelfhout, 2000). The condition is easily diagnosed histologically by punch biopsy or excision of the affected nipple tip after nipple-areolar blockade using local anesthetic. Evaluation also includes careful clinical examination, as an associated mass is identified in approximately 60 percent of cases (Ashikari, 1970). Among those with no palpable abnormalities, mammography will show suspicious densities or calcifications in 21 percent (Ikeda, 1993). An underlying DCIS is identified in about two thirds of cases, and an invasive cancer in approximately one third (Ashikari, 1970).

Treatment includes wide excision to achieve negative margins. Breast conservation requires central breast resection including the nipple-areolar complex and all identifiable underlying disease. Resection is followed by postoperative breast irradiation (Bijker, 2001). Axillary staging by SLN biopsy is not required unless an invasive component is identified or total mastectomy is performed.

BREAST CANCER RISK FACTORS

The most profound breast cancer risk factor is female gender. In addition, the incidence of breast cancer, as for most other cancers, increases with advancing age. Only 12 to 30 percent of breast cancer has a significant familial component, and apart from radiation exposure early in life, convincing environmental causes have not been elucidated (Baker, 2005; Locatelli, 2004). Breast cancer risk factors are listed in Table 13-3. In general, all of these risk factors are more prevalent in developed countries than in less-developed ones. Consequently, breast cancer is more common in industrialized cultures (Parkin, 2001).

Reproductive Factors

Ovulatory Cycles

Ovulatory menstrual cycles exert stress on the breast epithelium by inducing proliferation in the late luteal phase. If conception

TABLE 13-3. Common Risk Factors and Their Risk Ratios[a]

Genetic Risk Factors	Risk Ratio
Female gender	114
Age	4–158[b]
High-penetrance mutations: *BRCA1*, *BRCA2*, *p53*, *STK11*	26–36
Modest-penetrance mutations: *PTEN*, *p16*, *PALB2*, *CDH1*, *NF1*, *CHEK2*, *ATM*, *BRIP1*	2.0–2.7
Family: mother, daughter, sister	1.55–1.8
Family: aunt, niece, grandmother	1.15
Genetic polymorphisms: *FGFR2*, *TNRC9*, *MAP3K1*, *LSP1*, *MRPS30*	1.07–1.26
Other Factors	
Mantle radiation	5.6
Acini per lobule in benign breast tissue	
11–20	2.8
21–40	3.23
≥41	11.85
Mammographic density	
>25–50% (scattered)	2.4
>51–75% (heterogeneous)	3.4
>75% (dense)	5.3
Biopsy w LCIS	5.4
Biopsy w atypical hyperplasia	5
Increased BMD	2.0–2.5
Age at first birth >35	1.31–1.93
Obesity (BMI >30)	1.2–1.8
Any benign breast disease	1.47
Elevated circulating insulin	1.46
5 years of combined HRT	1.26–1.76
Elevated circulating estrogen	1.1–1.7
Nulliparity	1.26–1.55
Alcohol (>1 drink/day)	1.31
Age at menarche <12	1.21

[a]Risks listed by genetic or nongenetic and ordered by strength of association with breast cancer.
[b]Risk compared with women aged 20–29. The risk ratio increases approximately by 4 for every year older than 30.
BMD = bone mineral density; BMI = body mass index; HRT = hormone replacement therapy; LCIS = lobular carcinoma in situ.
Compiled from Beral, 2011; Bodian, 1996; Cauley, 1996; Claus, 1994; De Bruin, 2009; Easton, 2007; Freisinger, 2009; Fu, 2007; Gail, 1989; Gunter, 2009; Hankinson, 2005; Hulley, 2002; Kotsopoulos, 2010; Lalloo, 2006; Mavaddat, 2010; McKian, 2009; Phipps, 2010; Rossouw, 2002; Santen, 2005; Welsh, 2009; Zhou, 2011.

does not occur, proliferation is followed by programmed cell death (Anderson, 1982; Soderqvist, 1997). Early age at menarche is associated with earlier onset of ovulatory cycles and higher breast cancer risk (den Tonkelaar, 1996; Vihko, 1986). Conversely, early menopause, whether it is natural or surgical, is associated with a reduced breast cancer risk (Kvale, 1988). Pregnancy generates very high levels of circulating estradiol, which is associated with a transient rise in short-term risk. But pregnancy also induces terminal differentiation of breast epithelium and provides relief from ovarian cycling. Consequently, increasing parity is associated with reduced lifetime risk.

Pregnancy

The breast is unique among all human organs in that it exists as a primordium for a decade or more before entering a highly proliferative state at menarche, and then does not fully mature until the first live birth. Immature breast epithelium is more susceptible to carcinogens than postlactational epithelium (Russo, 1996). Thus, the longer a first live birth is delayed, the greater the breast cancer risk is. Specifically, a first live birth before the age of 28 years is associated with reduced breast cancer risk, whereas one occurring later is associated with elevated risk (Gail, 1989). Both early age at first live birth and greater numbers of live births are associated with a lower breast cancer risk (Layde, 1989; Pike, 1983).

Hormone Replacement Therapy

The postmenopausal use of combined estrogen and progestin hormone replacement therapy is a modest breast cancer risk factor, and relative risks range from 1.26 to 1.76 (Beral, 2011; Hulley, 2002; Rossouw, 2002). The risk is higher with longer durations of use and with a shorter interval between the onset of menopause and the start of the medication (Beral, 2011). Estrogen-only replacement is not convincingly associated with an increased breast cancer risk. However, a relationship between estrogen-only therapy and body mass index yields a lower risk for obese women and higher risk for thin women (Anderson, 2004).

BREAST CANCER RISK STRATIFICATION AND MANAGEMENT

Approaches for managing breast cancer risk include: (1) lifestyle modification to achieve and sustain ideal body weight, (2) enhanced surveillance that includes screening MR imaging, (3) chemoprevention with a selective estrogen-receptor modifier (SERM) or an aromatase inhibitor, and (4) prophylactic surgery that includes oophorectomy or mastectomy for those at highest risk (Cuzick, 2014; Domchek, 2010; Goss, 2011; Heemskerk-Gerritsen, 2007; Vogel, 2010). Beyond beneficial lifestyle modification, each intervention introduces new risks, and thus breast cancer risk quantification is essential for decision making.

The American Cancer Society has endorsed screening MR imaging for women with a lifetime breast cancer risk that exceeds 20 percent (Saslow, 2010). The Food and Drug Administration (FDA) has approved tamoxifen chemoprevention for women

older than 35 years with >1.7 percent breast cancer risk over 5 years. Similarly, the SERM raloxifene (Evista) is approved for increased-risk postmenopausal women. To maximize benefit and minimize harm, breast cancer risk, age, race, and prior hysterectomy all factor into chemoprevention decisions (Freedman, 2011).

The foregoing highlights the importance of quantitative breast cancer risk stratification. Several computer models are available for this. The most widely used are the Gail model, available at www.cancer.gov/bcrisktool/ and the IBIS (Tyrer-Cuzick) model available at www.ems-trials.org/riskevaluator/ (Costantino, 1999; Gail, 1989; Rockhill, 2001; Tyrer, 2004). The Gail model is insufficient when there is a strong family history of breast cancer, male breast cancer, or ovarian cancer (Euhus, 2002). Genetic models such as BRCAPRO, Tyrer-Cuzick, or BOADICEA are more appropriate in these settings (Berry, 1997; Lee, 2014; Tyrer, 2004).

Breast Cancer Genetics

Twin studies suggest that only 12 to 30 percent of breast cancer is primarily genetic in origin, and modeling studies implicate autosomal dominant inheritance of single genes as the most important mechanism (Lichtenstein, 2000; Locatelli, 2004; Risch, 2001). Accordingly, genetic testing is one of the most powerful risk stratification tools available. It can identify women at very high risk for cancer who could reasonably consider risk-reducing surgery. In breast cancer patients, it can also contribute directly to decisions regarding surgery, radiation, and systemic therapies (Euhus, 2013). Mutations in *BRCA1*, *BRCA2*, *PALB2*, *CHEK2*, and *ATM* genes are the most frequently identified germline alterations in familial breast cancer, but the list of predisposition genes is growing (Table 13-4). Commercialized massive parallel sequencing, namely, next-generation sequencing, now allows testing for mutations in a few to dozens of genes simultaneously (Euhus, 2015).

Obtaining a reasonably detailed cancer family history is essential for identifying individuals who may benefit from genetic counseling and testing. At a minimum, the relationship and age at diagnosis is recorded for every cancer in the family. Family histories that may suggest inherited susceptibility include early-onset breast cancer (<50 years), bilateral breast cancer, male breast cancer, multiple affected relatives in one generation, breast cancer in multiple generations, development of cancers that are known to be associated with a particular syndrome, and two or more cancers in one relative, especially if they develop at an early age.

TABLE 13-4. Genetic Syndromes Associated with Increased Breast Cancer Risk

Syndrome Name	Genetic Mutation
Hereditary breast-ovarian cancer syndrome	*BRCA1*, *BRCA2*
Li-Fraumeni	*p53*
Cowden	*PTEN*
Peutz-Jegher	*STK11*
Hereditary diffuse gastric cancer	*CDH1*
PALB2	*PALB2*
ATM	*ATM*
CHEK2	*CHEK2*
RAD51C	*RAD51C*

Hereditary Breast-Ovarian Cancer Syndrome

This syndrome accounts for 5 to 7 percent of breast cancers in the United States and is most frequently caused by *BRCA1* or *BRCA2* mutation (Malone, 2000). With *BRCA1* mutations, hallmarks include early age at breast cancer diagnosis (median 44 years); high-grade, estrogen-receptor– and progesterone-receptor–negative breast cancers; and associated ovarian cancer (Foulkes, 2004).

For *BRCA1* mutation carriers, the lifetime breast cancer risk ranges from 45 to 81 percent, and ovarian cancer risk from 16 to 54 percent (Antoniou, 2008; Brohet, 2014; Ford, 1998; King, 2003; Mavaddat, 2013). Individuals who have developed both breast and ovarian cancer have an 86-percent probability of carrying a *BRCA* mutation (Cvelbar, 2005).

Among *BRCA2* carriers, lifetime risk for breast cancer ranges from 27 to 85 percent, and ovarian cancer risk from 6 to 27 percent. Women with *BRCA2* mutations develop breast cancer later in life than *BRCA1* carriers, thus age at diagnosis is not usually a good criterion for recognizing this syndrome (Panchal, 2010). Similar to sporadic breast cancer, most *BRCA2*-associated breast cancers are hormone receptor–positive (Lakhani, 2002). Ovarian cancer is an associated cancer but develops less frequently than it does in *BRCA1*-affected families. Five to 13 percent of male breast cancers are associated with *BRCA2* mutations. For men, lifetime breast cancer risk is estimated at 1.8 percent with *BRCA1* mutations and 8.3 percent for *BRCA2* (Tai, 2007).

For affected women, early premenopausal bilateral oophorectomy reduces breast cancer risk by 37 to 72 percent and also lowers breast cancer–specific and all-cause mortality rates (Domchek, 2010; Finch, 2014; Kauff, 2008). This is discussed further in Chapter 35 (p. 736). Bilateral prophylactic mastectomy reduces breast cancer risk by more than 90 percent but does not appear to improve survival rates (Hartmann, 2001; Heemskerk-Gerritsen, 2007; Meijers-Heijboer, 2001).

With the introduction of next-generation sequencing panel tests, clinicians are increasingly confronted with rare syndromes for which data to guide management are limited (see Table 13-4) (Euhus, 2015). Involvement of professional genetic counselors and careful assessment of a three-generation family cancer history are essential for estimating and managing cancer risk.

Surgical options for breast cancers that arise in the context of an inherited predisposition syndrome are the same as for sporadic breast cancers (Pierce, 2010). However, patients are counseled that the lifetime risk for contralateral breast cancer risk may be as high as 83 percent for *BRCA1* mutation carriers and 62 percent for *BRCA2* carriers. Retrospective data suggest that bilateral mastectomy may improve survival rates for these women (Evans, 2013; Mavaddat, 2013; Metcalfe, 2014).

BREAST CANCER SCREENING

In the United States, digital mammography has largely replaced film-screen mammography, and three-dimensional (3-D) tomosynthesis is gradually replacing two dimensional (2-D) mammography. This technique generates hundreds of images as the x-ray source arcs over the top of the breast. Digital reconstruction allows a radiologist to visually scroll through breast images and also significantly attenuates overlying breast densities at each level (Kopans, 2013). Compared with 2-D mammography, tomosynthesis reduces the false-positive rate (recall rate) by 15 to 30 percent and raises the cancer detection rate by 10 to 29 percent (Greenberg, 2014; Haas, 2013; Skaane, 2013). This is achieved with slightly higher radiation doses (Feng, 2012).

The Screening Mammography Controversy

In 2009, for women not at high risk for breast cancer, the U.S. Preventive Services Task Force recommended biennial screening mammography for women aged 50 to 74 years and individualized screening decisions for women aged 40 to 49. Nevertheless, several influential organizations including the American Cancer Society, the American College of Obstetricians and Gynecologists (2017), and the American College of Radiology have recommended that yearly screening mammography begin earlier (Monticciolo, 2017; Smith, 2018). The American College of Obstetricians and Gynecologists (2017) recommends offering annual or biennial screening beginning at age 40 years or at least by no later than age 50. The controversy centers on: (1) the true mortality rate benefit, (2) the harm from false-positive results, and (3) the harm from diagnosing clinically irrelevant breast cancers.

However, most data available for addressing these issues are derived from eight large, but older, randomized prospective trials. The most recent trial was completed in the 1980s. Recent technologic advances have significantly improved the sensitivity of mammography. However, breast cancer treatment has also advanced, reducing the mortality rate improvement from early detection. Based on 30-year-old data, it is generally agreed that screening mammography starting at age 50 reduces breast cancer mortality rates by approximately 27 percent, and one meta-analysis reported an 18-percent reduction for women aged 40 to 49 (Hendrick, 1997; Kerlikowske, 1997). However, screen-detected breast cancer is a heterogeneous disease. Some cancers will eventually develop clinical metastases no matter how small they are when first detected, and some will never become lethal no matter how long diagnosis is delayed. This latter form is the one most likely to be detected by periodic screening (length time bias).

The practice of screening mammography is based on the assumption that early intervention in some subgroup of tumors will interrupt progression and save lives. Since screening mammography inception, the detection of early-stage breast cancer has significantly risen, but the diagnosis of node-positive or metastatic disease has shown only a small decline (Bleyer, 2012). This suggests that many breast cancers will never progress (overdiagnosed) and that the fraction of breast cancers whose progression can be interrupted by surgery may be modest.

For now, annual mammography beginning at age 40, as recommended by several professional societies, is reasonable. But, women are counseled of the risks and benefits. Among 1000 U.S. women aged 50 years who are screened annually for a decade, 0.3 to 3.2 are estimated to avoid a breast cancer death, 490 to 670 will have at least 1 false alarm, and 3 to 14 will be overdiagnosed and treated needlessly (Welch, 2014). There is no arbitrary age above which screening should cease. Women should have at least 10 years of remaining life to realize a mortality benefit from screening mammography (Lee, 2013).

Women who are at high risk for breast cancer because of a breast cancer predisposition mutation, a strong family history of breast cancer, or a personal history of high-risk preneoplasia such as ADH, ALH, or LCIS often participate in enhanced surveillance. This consists of semiannual imaging that alternates mammography and breast MR imaging. MR imaging screening may start as early as age 25 for mutation carriers, but annual mammography is delayed until after age 30.

Breast Magnetic Resonance Imaging

Breast MR imaging is commonly used as an adjunct to screen high-risk women and to establish disease extent in certain breast cancer patients. It is more sensitive for breast cancer detection than is mammography, but it is expensive and has a high false-positive rate. In addition, some evidence links its use with higher mastectomy rates but without reducing reexcision rates or improving breast cancer outcome (Houssami, 2013, 2014; Pilewskie, 2014; Turnbull, 2010).

As noted, annual screening breast MR imaging is frequently selected for genetically high-risk women and in women with a lifetime breast cancer risk exceeding 20 percent (Saslow, 2010). This raises the diagnosis of smaller, lymph node–negative breast cancers but does not improve survival rates (Gareth, 2014; Moller, 2013).

Breast MR imaging should not be routinely performed in women with newly diagnosed breast cancer, but it is recommended for women with mammographically dense breasts. Its primary value is assessing response to neoadjuvant chemotherapy in women contemplating breast conservation and in evaluating women with breast cancer metastatic to axillary lymph nodes from an unknown primary (Morrow, 2011). Additionally, it can aid establishing the extent of disease prior to breast conservation for a subset of patients in whom uncertainty persists after careful clinical examination, mammography, and sonography.

Other Breast Imaging Modalities

Adding almost any imaging modality to screening mammography will incrementally raise the cancer detection rate but at the cost of a higher false-positive rate and more biopsies. Modalities that are occasionally useful, but not recommended for routine use, include screening sonography, breast-specific gamma imaging, and breast positron emission tomography (PET) (Kalinyak, 2014; Merry, 2014; Rechtman, 2014). These last two tests are associated with significantly higher radiation

exposure. Evidence is accumulating that medical radiation exposure before age 30 can elevate breast cancer risk, and thus caution is advised (Berrington de Gonzalez, 2009; Pijpe, 2012).

Screening Physical Examination

The value of a screening clinical breast examination (CBE) performed by health care providers should not be neglected (Jatoi, 2003). Four of the large, randomized mammography trials mentioned earlier collected information on CBE and found that 44 to 74 percent of the breast cancers were detected by this approach. Among young women, sensitivity and specificity were higher for CBE than mammography.

In contrast, enthusiasm for patients to perform breast self-examination (BSE) has diminished after a large randomized trial from Shanghai found no improvement in mortality rates (Thomas, 2002). Although there is less interest in promoting regimented BSE, encouraging women to remain breast-aware is reasonable.

INVASIVE BREAST CANCER

In the United States, breast cancer is the most common cancer in women and the second most frequent cause of cancer-related mortality (second to lung) (Siegel, 2019). Although the incidence of breast cancer rose steadily in this country through the 1980s and 1990s, it has leveled at approximately 125 cases per year per 100,000 postmenopausal women and is declining for some ethnicities. Concurrently, survival rates steadily improve (Fig. 13-15).

Tumor Characteristics

Primary cancers of the breast constitute 97 percent of malignancies affecting the breast, whereas 3 percent represent metastases from other sites. The most common of these, in descending order, are the contralateral breast, sarcoma, melanoma, serous epithelial ovarian cancer, and lung cancer (DeLair, 2013). Cancers of mammary epithelial structures account for most of primary breast cancer. Infiltrating ductal carcinoma is the most common form of invasive breast cancer (~80 percent), and infiltrating lobular carcinoma is the second most frequent (~15 percent). Other malignancies such as phyllodes tumors, sarcoma, and lymphoma account for the remainder.

Apart from stage, the primary tumor characteristics that most influence prognosis and treatment decisions are hormone receptor status, nuclear grade, and Her-2/neu expression (Harris, 2007). Approximately two thirds of breast cancers are estrogen-receptor–positive and progesterone-receptor–positive. This feature is generally associated with a better prognosis and more treatment options.

Her-2/neu is a membrane tyrosine kinase that cooperates with other Her-family receptors to generate proliferation and survival signals in breast cancer cells. Approximately 20 percent of breast cancers have elevated expression of Her-2/neu (Masood, 2005). The list of medications that specifically target Her-2/neu overexpressing breast cancer is growing and includes trastuzumab (Herceptin), trastuzumab emtansine (Kadcyla), pertuzumab (Perjeta), neratinib (Nerlynx), and lapatinib (Tykerb) (Tolaney, 2014).

Gene expression profiling has identified several "intrinsic subtypes" of breast cancer with prognostic significance (Cadoo, 2013). Multigene assays are now available in the clinic for individualized prediction of prognosis and treatment response, especially for estrogen-receptor–positive tumors (Rouzier, 2013).

Breast Cancer Staging

Careful breast cancer staging is essential for predicting outcome, planning treatment, and comparing treatment effects in clinical trials. Each patient is assigned both a clinical and a pathologic stage. The clinical stage is based on examination and radiographic findings, whereas the pathologic stage is based on actual tumor measurements and histologic assessments of lymph nodes after primary surgery. Staging of breast cancer is based on anatomic features such as tumor size (T) and metastases to lymph nodes (N) or distant organs (M) and on the biologic features of the tumor. In 2018, the American Joint Committee on Cancer (AJCC) introduced this updated breast cancer staging system to better reflect true tumor behavior for treatment planning (Giuliano, 2017). The AJCC system incorporates additional prognostic factors to the TNM system. Biologic aspects are estrogen-receptor, progesterone-receptor, and HER-2/neu status; tumor grade; and sometimes the results of a molecular prognostic assay. The TNM information provides an anatomic stage, which may be adjusted to a higher or lower prognostic stage based on these biologic features.

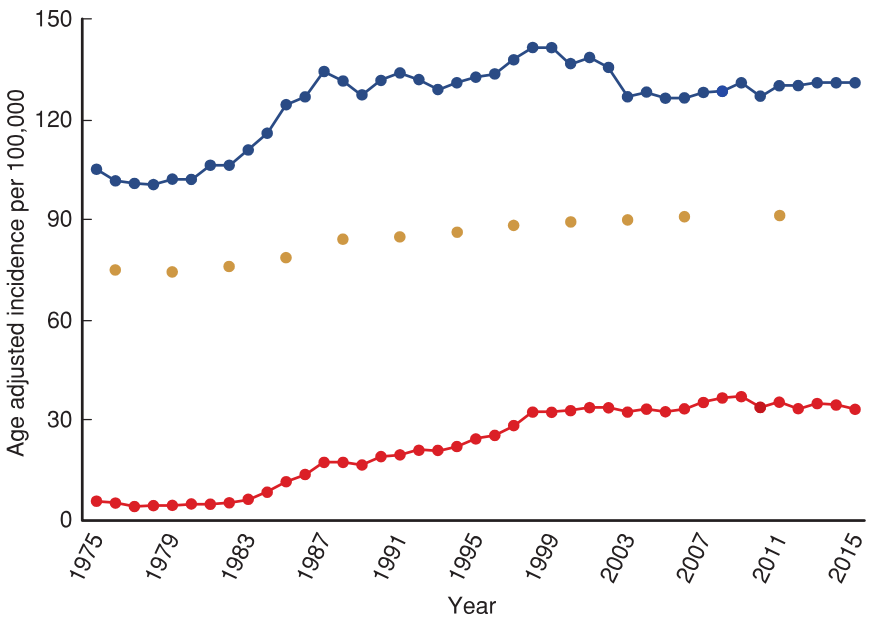

FIGURE 13-15 Trends in breast cancer incidence and survival in the United States. Curve of decreasing breast cancer rates in U.S. ● = incidence of invasive breast cancer; ● = incidence in situ; ● = 5-year survival.

The most common distant metastatic site in breast cancer is bone, followed by lung, liver, and brain. Thus, for newly diagnosed breast cancer patients, a complete blood count and liver function tests including alkaline phosphatase are recommended. Whole-body screening with CT of the chest, CT or MR imaging of the abdomen and pelvis, and bone scan or whole-body PET/CT are recommended only for clinical suspicion of metastases or for patients with clinical stage III disease (National Comprehensive Cancer Network, 2018).

Breast Cancer Treatment

Breast cancer is best managed by a multidisciplinary team of breast surgeons, medical oncologists, and radiation oncologists. Goals of surgery and radiation therapy are elimination of all local or regional tumor in a way that maximizes cosmesis and minimizes the risk of local or regional recurrence. Some evidence supports these local modalities to reduce the risk of subsequent metastases and therefore increase survival rates (Darby, 2011). However, a significant proportion of patients with apparently localized disease have tumor cells detectable in their blood or bone marrow at diagnosis (Braun, 2005; Giuliano, 2011a). Tumor size, nodal metastases, and biomarker profiles are used to recognize women at greater risk for disseminated disease. These women receive systemic treatment with chemotherapy, hormone manipulation, or targeted therapies to reduce the risk of metastasis and death (Dowsett, 2010; Peto, 2012).

Surgery

Halstead (1894) revolutionized breast cancer treatment by demonstrating improved outcome for patients treated with radical mastectomy. However, results from later randomized clinical trials have appropriately fostered a trend toward less aggressive surgery. Specifically, lumpectomy with postoperative radiation therapy results in the same breast cancer survival rate as total mastectomy (Fisher, 2002).

Axillary dissection—that is, near-complete axillary lymphadenectomy—also was once a standard in staging and treatment, but its role is diminishing (Rao, 2013). The procedure is still indicated for patients with clinically node-positive disease at diagnosis. However, it is frequently omitted in selected patients with clinically negative nodes but positive sentinel nodes, because radiation therapy and systemic adjuvant therapies achieve the same low axillary recurrence rate and the same survival rate (Galimberti, 2013; Giuliano, 2010,2011b). When required, axillary dissection results in lymphedema in 15 to 50 percent of women, depending on how it is measured (Morrell, 2005). Dissection is also associated with persistent shoulder or arm symptoms in up to 70 percent (Kuehn, 2000).

Radiation Therapy

After breast-conserving surgery, whole breast radiation reduces local recurrence from approximately 5 percent per year to 1 percent per year, although it may be omitted in elderly patients with favorable tumors (Fisher, 2002; Hughes, 2013). Shorter courses of partial breast irradiation may be appropriate in selected patients (Smith, 2009). Postmastectomy chest wall radiation improves survival in women with high-risk lymph node–positive breast cancer (Overgaard, 1999; Ragaz, 2005). Recent clinical trial data are driving a marked increase use of extended field radiation therapy (Early Breast Cancer Trialists' Collaborative Group, 2014).

Chemotherapy

In the past, adjuvant chemotherapy was reserved for patients with nodal metastases and was always given after definitive surgery. However, randomized prospective trials show that adjuvant chemotherapy also improves survival rates for high-risk node-negative patients (Fisher, 2004a). Increasingly, however, the decision for chemotherapy is influenced by specific measures of tumor biology including results from multigene assays (Rouzier, 2013; Sparano, 2008).

If used, adjuvant chemotherapy is usually administered after primary surgery but before radiation therapy. Neoadjuvant chemotherapy is given prior to definitive surgery and is gaining popularity. Neoadjuvant chemotherapy permits assessment of a given tumor's sensitivity to the selected agents, and tumor shrinkage permits less aggressive surgery (von Minckwitz, 2013).

Modern breast cancer chemotherapy often includes an anthracycline such as doxorubicin (Adriamycin) in conjunction with cyclophosphamide (Cytoxan) (Trudeau, 2005). The addition of a taxane has been shown to improve outcome (A'Hern, 2013). Platins such as cisplatin (Platinol) or carboplatin (Paraplatin) are increasingly used to replace doxorubicin when other cardiotoxic drugs such as trastuzumab are required. Platin may also be selected to treat certain tumor subtypes that have defects in homologous recombination, such as tumors associated with a *BRCA1* or *BRCA2* mutation. Chemotherapeutic agents are described more fully in Chapter 27 (p. 587).

Hormonal Therapy and Targeted Therapies

Adjuvant hormonal therapy is used for estrogen-receptor–positive tumors. In pre- or postmenopausal women, one option is the SERM tamoxifen (Jaiyesimi, 1995). As discussed in Chapter 27 (p. 598), important side effects of tamoxifen include menopausal symptoms, greater risk of thromboembolic events, and higher rates of endometrial polyps and endometrial cancer. Although this cancer risk is elevated, surveillance of the endometrium with routine transvaginal sonography or endometrial biopsy is not recommended. Endometrial evaluation is reserved for those with abnormal bleeding and follows that outlined in Chapter 8 (p. 182).

In postmenopausal women, aromatase inhibitors may be used. FDA-approved agents include anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin) (Kudachadkar, 2005). In postmenopausal women, most circulating estradiol is derived from the peripheral conversion of androgens by the enzyme aromatase. Administration of aromatase inhibitors reduces circulating estradiol to nearly undetectable levels in these women. The addition of an aromatase inhibitor after tamoxifen is associated with a 23- to 39-percent improvement in the disease-free survival rate and a nearly 50-percent reduction in the contralateral breast cancer rate (Geisler, 2006). Although

FIGURE 13-16 Photographs of inflammatory breast cancer. **A.** Subtle erythematous blush and edema in inflammatory breast cancer. **B.** Classic inflammatory breast cancer. (Reproduced with permission from Dr. Marilyn Leitch.)

tamoxifen is commonly used as an initial antihormonal therapy in postmenopausal women, transition to an aromatase inhibitor improves outcome (Johnston, 2014).

Unlike tamoxifen, aromatase inhibitors are associated with greater rates of bone loss and fractures. Accordingly, baseline bone mineral density testing and periodic monitoring is recommended. For women with mild or moderate bone loss, exercise and supplementation with vitamin D and calcium are encouraged. Various agents are available for managing severe loss, and a discussion of these drugs is found in Chapter 22 (p. 491).

Bisphosphonates such as zoledronic acid (Zometa) are often used to prevent cancer treatment–induced bone loss (Hadji, 2011). In addition, the combination of aromatase inhibitors and zoledronic acid appears to improve outcome in hormone receptor–positive breast cancer (Coleman, 2013).

Her-2/neu is currently the only target routinely exploited in the adjuvant therapy of early-stage breast cancer. However, other therapies that target specific biological pathways are improving outcomes, especially for metastatic breast cancer. Beyond tamoxifen and aromatase inhibition, advanced estrogen-receptor–positive breast cancer can be treated with the estrogen-receptor antagonist fulvestrant (Faslodex), by inciting cell cycle blockade with one of the several CDK4/6 inhibitors, or by inhibiting the mTOR pathway with everolimus (Afinitor) (Andre, 2014; Dhillon, 2013). Tumors that lack estrogen receptors, progesterone receptors, and Her-2/neu, so-called triple-negative breast cancers, have long been recognized as treatment resistant, but progress is being made. It is increasingly recognized that subsets of triple-negative breast cancer are sensitive to platinum-based chemotherapy, to poly ADP ribose polymerase (PARP) inhibition, and to immune checkpoint blockade. Comprehensive molecular profiling of tumors to identify targets for intervention is becoming more common but only rarely yields a clinically useful result (Frampton, 2013). These biologic agents for targeting cancer are described in Chapter 27 (p. 600).

Surveillance

Long-term surveillance of breast cancer patients after treatment includes periodic history and physical examination. Women who elect breast conservation are counseled that the remaining breast tissue requires surveillance indefinitely. Rates of ipsilateral or contralateral second primary breast cancers have been declining and now average 0.2 percent per year (Nichols, 2011). Rates are higher for younger patients and patients with estrogen receptor–negative disease. Laboratory and imaging tests are obtained to further evaluate specific signs or symptoms. Screening tests other than annual mammography to identify asymptomatic recurrences are not recommended (Khatcheressian, 2013).

Inflammatory Breast Cancer

Inflammatory breast cancer accounts for 1 to 5 percent of breast cancers (Chang, 1998; Dawood, 2010). This cancer presents with skin changes that can range from a faint red blush to a flaming-red rash associated with skin edema (peau d'orange change) (Fig. 13-16). It is distinguished from a neglected advanced primary breast cancer by its rapid onset and progression within just a few weeks. The cancer spreads rapidly throughout the entire breast and creates diffuse induration. As a result, the breast may enlarge to two to three times its original volume within weeks (Taylor, 1938).

Although mastitis or even congestive heart failure can produce a similar clinical appearance, inflammatory breast cancer must be definitively excluded. This always includes diagnostic mammography and punch biopsy of the skin. However, it also may require multiple biopsies and additional imaging such as MR imaging. Treatment begins with induction chemotherapy, followed by modified radical mastectomy (total mastectomy and axillary dissection). This is followed by postoperative chest wall irradiation with or without additional chemotherapy (Cariati, 2005). The 5-year survival rate is 30 to 55 percent, which is significantly worse than for neglected advanced primary breast cancer (Brenner, 2002; Harris, 2003).

REFERENCES 316

Thirty years ago, psychiatrist George Engel coined a term to describe a developing paradigm for patient care, the "biopsychosocial model" (Engel, 1977). In the years since, this model has also incorporated cultural and spiritual factors. When conceptualizing a woman's understanding of her reproductive events, this model highlights the distinction between disease, a pathologic process, and illness, a patient's experience of that process. At times, psychologic health is linked directly with reproductive health. As an example, infertility can lead to mood and anxiety disorders. In contrast, preexisting psychologic distress might be an insidious cause of a health problem. For example, higher hysterectomy rates are noted in women with a low tolerance for the physical discomfort of menstruation.

Years before Engel's work, Erik Erikson (1963) created a model that describes psychologic maturation in stages across the life span. Specifically, adolescents are confronted with identity development; reproductive-aged women with intimacy concerns; peri- and early menopausal women with productivity issues; and older women with life review. Combining Erikson's developmental model with a biopsychosociocultural model provides a dimensional perspective to aid evaluation, diagnosis, and treatment of any patient.

Most patients with psychiatric illness are first seen in primary care settings, and gynecologists often are the first to evaluate a woman with psychiatric distress. The clinical interview in Table 14-1 provides an example of an assessment that includes all domains from the biopsychosociocultural model.

MOOD DISORDERS

Mood, anxiety, and alcohol or substance use disorders are three families of psychiatric disorders commonly seen and often comorbid with reproductive events. These three groups are defined by specific criteria described by the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) (American Psychiatric Association, 2013). Each family of disorders is characterized by predominant features, and each disorder within those families is identified by specific symptoms of that feature.

Of these families, mood disorders are categorized as *depressive disorders* (major depressive disorder, persistent depressive

TABLE 14-1. Psychiatric Assessment of Women

Component	Consideration
Present or past psychiatric illness	Relation to reproductive triggers: pregnancy, menses, menopause, etc.
Medications	All medications and supplements; exogenous hormones
Diet	Abnormal eating patterns; diet pills, laxatives, diuretics
Substance use	Covert use, particularly prescription drugs
Family history	Including reproductive event–related symptoms/disorders
Medical history	Autoimmune disease, which can present with psychiatric symptoms
Reproductive history	Premenstrual, pregnancy, pregnancy loss, postpartum or perimenopausal context of symptoms
Social	Current or past sexual, physical, or emotional abuse. Note sexual preference and current relationship satisfaction
Cultural	Norms and beliefs of community/family
Spiritual	Rituals, guidelines, and attributes of a "good" life
Economic	Ability to meet ongoing financial needs

TABLE 14-2. Diagnostic Criteria for a Major Depressive Episode

A. ≥5 criteria present during the same 2-week period and represent change from previous functioning. At least one of these is:
Depressed mood most of the day, nearly every day
Markedly diminished interest/pleasure in most activities, most of the day, most days

The balance of 5 from these:
Significant weight loss/gain, change in appetite, or failure to make expected gains
Insomnia or hypersomnia nearly every day
Psychomotor agitation or retardation nearly every day, *observable by others*
Fatigue or loss of energy nearly every day
Feelings of worthlessness or excessive or inappropriate guilt nearly every day
Diminished ability to think or concentrate or indecisiveness
Recurrent thoughts of death, recurrent suicidal ideation, plans, or attempt

B. Symptoms cause significant distress or impairment in functioning
C. Symptoms are not due to a substance or a general medical condition
D. Symptoms not accounted by other psychiatric disorder
E. No prior mania or hypomania

Data from American Psychiatric Association, 2013.

disorder, premenstrual dysphoric disorder, other specified depressive disorder, and unspecified depressive disorder) or as *bipolar and related disorders* (bipolar I, bipolar II, cyclothymic disorder, other specified bipolar disorder, and unspecified bipolar disorder). Bipolar disorders are first characterized by abnormally and persistently elevated, expansive, or irritable mood (sometimes described as "energy") alternating with depressed mood. Other characteristics are impulsiveness, high-risk behavior, and difficulty sleeping. As with all psychiatric disorders, these characteristics must represent a change in functioning and be severe enough to impair occupational or social relationships.

For depressive disorders, symptoms include those in Table 14-2. The lifetime prevalence in the general U.S. population approximates 20 percent (Kessler, 2005; National Institute of Mental Health, 2016). As such, depression is a major cause of disability, and females are 1.6 times more likely than males to suffer from a major depressive episode (Substance Abuse and Mental Health Services Administration, 2013). Women also may experience one or more comorbid psychiatric disorders, most often an anxiety disorder and/or substance use disorder.

Self-report questionnaires are generally used to identify individuals who require further psychiatric evaluation (screening measures) and may also assess the frequency and intensity of depressive symptoms (severity measures). The Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR) is one such tool easily implemented for clinical use (Tables 14-3 and 14-4)

TABLE 14-3. The Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report) (QIDS-SR$_{16}$)

CHECK THE ONE RESPONSE TO EACH ITEM THAT BEST DESCRIBES YOU FOR THE PAST SEVEN DAYS.

During the past seven days…

1. Falling Asleep:
☐ 0 I never take longer than 30 minutes to fall asleep.
☐ 1 I take at least 30 minutes to fall asleep, less than half the time.
☐ 2 I take at least 30 minutes to fall asleep, more than half the time.
☐ 3 I take more than 60 minutes to fall asleep, more than half the time.

2. Sleep During the Night:
☐ 0 I do not wake up at night.
☐ 1 I have a restless, light sleep with a few brief awakenings each night.
☐ 2 I wake up at least once a night, but I go back to sleep easily.
☐ 3 I awaken more than once a night and stay awake for 20 minutes or more, more than half the time.

3. Waking Up Too Early:
☐ 0 Most of the time, I awaken no more than 30 minutes before I need to get up.
☐ 1 More than half the time, I awaken more than 30 minutes before I need to get up.
☐ 2 I almost always awaken at least one hour or so before I need to, but I go back to sleep eventually.
☐ 3 I awaken at least one hour before I need to, and can't go back to sleep.

4. Sleeping Too Much:
☐ 0 I sleep no longer than 7–8 hours/night, without napping during the day.
☐ 1 I sleep no longer than 10 hours in a 24-hour period including naps.
☐ 2 I sleep no longer than 12 hours in a 24-hour period including naps.
☐ 3 I sleep longer than 12 hours in a 24-hour period including naps.

(Continued)

TABLE 14-3. The Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report) (QIDS-SR$_{16}$) *(Continued)*

During the past seven days…

5. Feeling Sad:
- ☐ 0 I do not feel sad.
- ☐ 1 I feel sad less than half the time.
- ☐ 2 I feel sad more than half the time.
- ☐ 3 I feel sad nearly all of the time.

Please complete either 6 or 7 (not both)

6. Decreased Appetite:
- ☐ 0 There is no change in my usual appetite.
- ☐ 1 I eat somewhat less often or lesser amounts of food than usual.
- ☐ 2 I eat much less than usual and only with personal effort.
- ☐ 3 I rarely eat within a 24-hour period, and only with extreme personal effort or when others persuade me to eat.

-OR-

7. Increased Appetite:
- ☐ 0 There is no change from my usual appetite.
- ☐ 1 I feel a need to eat more frequently than usual.
- ☐ 2 I regularly eat more often and/or greater amounts of food than usual.
- ☐ 3 I feel driven to overeat both at mealtime and between meals.

Please complete either 8 or 9 (not both)

8. Decreased Weight (Within the Last Two Weeks):
- ☐ 0 I have not had a change in my weight.
- ☐ 1 I feel as if I have had a slight weight loss.
- ☐ 2 I have lost 2 pounds or more.
- ☐ 3 I have lost 5 pounds or more.

-OR-

9. Increased Weight (Within the Last Two Weeks):
- ☐ 0 I have not had a change in my weight.
- ☐ 1 I feel as if I have had a slight weight gain.
- ☐ 2 I have gained 2 pounds or more.
- ☐ 3 I have gained 5 pounds or more.

During the past seven days…

10. Concentration/Decision-Making:
- ☐ 0 There is no change in my usual capacity to concentrate or make decisions.
- ☐ 1 I occasionally feel indecisive or find that my attention wanders.
- ☐ 2 Most of the time, I struggle to focus my attention or to make decisions.
- ☐ 3 I cannot concentrate well enough to read or cannot make even minor decisions.

11. View of Myself:
- ☐ 0 I see myself as equally worthwhile and deserving as other people.
- ☐ 1 I am more self-blaming than usual.
- ☐ 2 I largely believe that I cause problems for others.
- ☐ 3 I think almost constantly about major and minor defects in myself.

12. Thoughts of Death or Suicide:
- ☐ 0 I do not think of suicide or death.
- ☐ 1 I feel that life is empty or wonder if it's worth living.
- ☐ 2 I think of suicide or death several times a week for several minutes.
- ☐ 3 I think of suicide or death several times a day in some detail, or I have made specific plans for suicide or have actually tried to take my life.

13. General Interest:
- ☐ 0 There is no change from usual in how interested I am in other people or activities.
- ☐ 1 I notice that I am less interested in people or activities.
- ☐ 2 I find I have interest in only one or two of my formerly pursued activities.
- ☐ 3 I have virtually no interest in formerly pursued activities.

During the past seven days…

14. Energy Level:
- ☐ 0 There is no change in my usual level of energy.
- ☐ 1 I get tired more easily than usual.
- ☐ 2 I have to make a big effort to start or finish my usual daily activities (for example, shopping, homework, cooking, or going to work).
- ☐ 3 I really cannot carry out most of my usual daily activities because I just don't have the energy.

15. Feeling Slowed Down:
- ☐ 0 I think, speak, and move at my usual rate of speed.
- ☐ 1 I find that my thinking is slowed down or my voice sounds dull or flat.
- ☐ 2 It takes me several seconds to respond to most questions, and I'm sure my thinking is slowed.
- ☐ 3 I am often unable to respond to questions without extreme effort.

16. Feeling Restless:
- ☐ 0 I do not feel restless.
- ☐ 1 I'm often fidgety, wringing my hands, or need to shift how I am sitting.
- ☐ 2 I have impulses to move about and am quite restless.
- ☐ 3 At times, I am unable to stay seated and need to pace around.

TABLE 14-4. Quick Inventory of Depressive Symptomatology-Self Report ($QIDS\text{-}SR_{16}$) Scoring Instructions

1. Enter the highest score on any one of the four sleep items (items 1 to 4)
   Enter the highest score on any one of the four weight items (items 6 to 9)
   Enter the highest score on either of the two psychomotor items (items 15 and 16)
2. There will be one score for each of the nine Major Depressive Disorder symptom domains
3. Add the scores of the nine items (sleep, weight, psychomotor changes, depressed mood, decreased interest, fatigue, guilt, concentration, and suicidal ideation) to obtain the total score; total scores range from 0 to 27
4. 0–5: no depressive symptoms; 6–10: mild symptoms; 11–15: moderate symptoms; 16–20: severe symptoms; 21–27: very severe symptoms

From Rush, 2003.

(Rush, 2003). Further information regarding the instrument is available at www.ids-qids.org. By patient report, this questionnaire assesses symptom severity required by DSM-5 criteria to diagnosis major depressive disorder. Ultimately, diagnosing mood disorders requires assessment by a trained clinician.

ANXIETY DISORDERS

Anxiety disorders have the highest prevalence rates in the United States. Lifetime rates approximate 30 percent, and as with depression, women are 1.6 times more likely to be diagnosed than men (Kessler, 2005). Criteria established in the DSM-5 provide guidelines to help distinguish anxiety disorders from normally expected worries (Table 14-5).

SUBSTANCE USE DISORDERS

In the United States, the lifetime prevalence for alcohol and substance use disorders approximates 15 percent. This diagnosis is twice as likely in males, although rates in women are rising (Kessler, 2005). Indicators of substance misuse are found in Table 14-6. Often substance use disorders coexist with mood and anxiety disorders. Additional information regarding commonly abused substances is found at the National Institute on Drug Abuse website www.drugabuse.gov.

EATING DISORDERS

Specific feeding and eating disorders classified by the DSM-5 and relevant to women's health care are anorexia nervosa, bulimia nervosa, binge-eating disorder, and unspecified feeding or eating disorder (Tables 14-7 and 14-8). The core symptoms of both anorexia and bulimia are preoccupation with weight gain and excessive self-evaluation of weight and body shape, accompanied by either restriction of food intake (anorexia) or the use of compensatory behaviors to prevent weight gain after binge eating (bulimia). Binge-eating disorder is differentiated by consuming larger amounts of food, lacking a sense of control over the eating, but not engaging in subsequent weight-loss behaviors. These disorders are 10 to 20 times more common in females than in males, particularly in those aged 15 to 24 years (Mitchell, 2006). In young females, an estimated 4 percent suffer from anorexia, 1 to 1.5 percent from bulimia, and 1.6 percent from binge-eating disorder. While anorexia usually begins early in adolescence and peaks around age 17, bulimia nervosa typically has a later onset than anorexia and is more prevalent over the life span (Hoek, 2006). Pathologic eating is also found in older women, particularly binge-eating disorder and unspecified eating disorder (Mangweth-Matzek, 2014).

The exact etiology of such abnormal consumption is unknown. However, evidence suggests a strong familial aggregation for eating disorders (Trace, 2013). Twin studies yield estimates of heritability ranging from 28 to 74 percent for anorexia nervosa, 55 to 65 percent for bulimia nervosa, and 33 to 45 percent for binge-eating disorder (Hübel, 2018). Biologic, environmental, and psychologic factors all interact with and influence the expression of genetic risk (Culbert, 2015). Factors may include abnormalities in neuropeptides and neurotransmitter levels, altered hypothalamic-pituitary-adrenal and hypothalamic-pituitary-gonadal axes, and family and sociocultural

TABLE 14-5. Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry occurring more days than not for at least 6 months, about a number of events or activities
B. The person finds it difficult to control the worry
C. The anxiety and worry are associated with ≥3 of the following six symptoms:

Easily fatigued	Irritability
Muscle tension	Disturbed sleep
Difficulty concentrating	Restless or keyed up

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
E. The disturbance is not due to physiological effects of a substance or another medical condition
F. Symptoms not better explained by another mental disorder

Data from American Psychiatric Association, 2013.

TABLE 14-6. Diagnostic Criteria for Substance Use Disorder

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by two or more of the following, occurring at any time in the same 12-month period:
Consumption of larger amounts or over a longer period than was intended
Desire or unsuccessful efforts to cut down
Increased time spent in activities seeking the substance
Cravings or urges
Failure to fulfill major obligations
Continued use despite recurrent problems
Giving up important social, occupational, or recreational activities
Use in physically hazardous situations
Persistent use despite knowledge of problem
Tolerance develops to the substance
Substance cessation leads to withdrawal symptoms

Data from American Psychiatric Association, 2013.

influences (Stoving, 2001). Although previously thought to be culture-bound to the Western world, eating disorders appear to be distributed throughout the world (Kolar, 2016; Pike, 2015; Thomas, 2016).

Diagnosis

Anorexia nervosa is divided into two subtypes: (1) a restricting type and (2) a binge-eating/purging type, which is distinguished from bulimia by the patient weighing less than the minimum standard for normal. Symptoms begin as unique eating habits that become more and more restrictive. Advanced symptoms may include extreme food intake restriction and excessive exercise. Up to 50 percent of anorectics also show bulimic behavior, and these types may alternate during the course of anorexic illness. Bulimic-type anorectics have been found to engage in two distinct behavior patterns, those who binge and purge and those who solely purge.

Diagnosis of anorexia is initially challenging, as patients often defend their eating behaviors upon confrontation and rarely recognize their illness. They increasingly isolate themselves socially as their disorder progresses. Multiple somatic complaints such as gastrointestinal symptoms and cold intolerance are common. In the disorder's later stages, weight loss becomes more apparent, and medical complications may prompt patients to seek help. Findings often include dental problems, general nutritional deficiency, electrolyte abnormalities (hypokalemia and alkalosis), and decreased thyroid function. Electrocardiogram changes such as QT prolongation (bradycardia) and inversion or flattened T-waves may be noted. Rare complications include gastric dilation, arrhythmias, seizure, and death.

Bulimia nervosa is identified by periods of uncontrolled eating of high-calorie foods (binges), followed by compensatory behaviors such as self-induced vomiting, fasting, excessive exercise, or misuse of laxatives, diuretics, or emetics. Unlike patients with anorexia, those with bulimia often recognize their maladaptive behaviors. Severity is based on the frequency of the inappropriate behaviors, clinical symptoms, and level of disability. Most bulimics have normal weights, although their weight may fluctuate. Physical changes may be subtle and include dental problems, swollen salivary glands, or knuckle calluses on the dominant hand. Termed *Russell sign*, calluses form in response to repetitive contact with stomach acid or teeth during purging (Strumia, 2005).

Binge-eating disorder is distinct from anorexia and bulimia. It is characterized by ingesting large amounts of food within a short time and is accompanied by feelings that one cannot control the amount of food eaten. Severity is assessed according to the number of gorging episodes per week. Binge-eating is associated with obesity. That said, most obese individuals do not necessarily engage in binge episodes and consume comparatively fewer calories than those with the syndrome. Prevalence in

TABLE 14-7. Diagnostic Criteria for Anorexia Nervosa

A.	Refusal to maintain body weight at or above a minimal normal weight for age and height
B.	Intense fear of gaining weight or becoming fat, even though underweight
C.	Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low weight

Restricting Type: No binge-eating or purging behaviors

Binge-Eating/Purging Type: Binge-eating and self-induced vomiting, or the misuse of laxatives, diuretics, or enemas

Data from American Psychiatric Association, 2013.

TABLE 14-8. Diagnostic Criteria for Bulimia Nervosa

A. Recurrent episodes of binge eating
Eating, in a discrete period of time, an amount of food definitely larger than most people would eat in a similar period of time under similar circumstances
A sense of lack of control over eating during the episode
B. Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
C. Binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months
D. Self-evaluation is unduly influenced by body shape and weight
E. The disturbance does not occur exclusively during episodes of anorexia nervosa

Data from American Psychiatric Association, 2013.

the United States approximates 1.6 percent for females and 0.8 percent for males. In middle-aged women, binge-eating is more common than anorexia or bulimia (Mangweth-Matzek, 2014).

All these are complex disorders that affect both psychologic and physical systems and are often comorbid with depression and anxiety. Rates of mood symptoms approximate 50 percent, and anxiety symptoms, 60 percent (Braun, 1994). Simple phobia and obsessive-compulsive behaviors may coexist. In many cases, patients with anorexia have rigid, perfectionistic personalities and low sexual interest. Patients with bulimia often display sexual conflicts, problems with intimacy, and impulsive suicidal tendencies.

Treatment

A multidisciplinary approach benefits the treatment of eating disorders. Practice approaches include: (1) nutritional rehabilitation, (2) psychosocial treatment that includes individual and family therapies, and (3) pharmacotherapeutic treatment of concurrent psychiatric symptoms. Online resources for information and support are provided by the National Eating Disorder Association, www.edap.org and Academy for Eating Disorders, www.aedweb.org.

Data concerning the long-term physical and psychologic prognosis of women with eating disorders are limited. Most may symptomatically improve with aging. However, complete recovery from anorexia nervosa is rare, and many continue to have distorted body perceptions and peculiar eating habits. Overall, the prognosis for bulimia is better than for anorexia.

MENSTRUATION-RELATED DISORDERS

Frequently, reproductive-aged women experience symptoms during the late luteal phase of their menstrual cycle. Collectively these complaints are termed *premenstrual syndrome (PMS)* or, when more severe and disabling, *premenstrual dysphoric disorder (PMDD)*. Nearly 300 different symptoms have been reported and typically include both psychiatric and physical complaints. For most women, these are self-limited. However, approximately 15 percent report moderate-to-severe complaints that cause some impairment or require special consideration (Wittchen, 2002). Current estimates are that 3 to 8 percent of menstruating women meet the strict criteria for PMDD (Halbreich, 2003b).

Pathophysiology

Still under investigation, PMDD is thought to spring from genetic factors, psychosocial factors (particularly stress), and an altered sensitivity to the normal hormonal fluctuations that influence CNS functioning (Hantsoo, 2015). Because of the timing of symptoms, current thinking is that hormonal fluctuation is the key trigger.

First, estrogen and progesterone are integral to the menstrual cycle. The cyclic complaints of PMS begin following ovulation and resolve with menses. PMS is less common in women with surgical oophorectomy or drug-induced ovarian hypofunction, such as with gonadotropin-releasing hormone (GnRH) agonists (Cronje, 2004; Wyatt, 2004). Moreover, women with anovulatory cycles appear protected. One potential effect stems from estrogen and progesterone's influence on CNS neurotransmitters: serotonin, noradrenaline, and gamma-aminobutyric acid (GABA). The predominant action of estrogen is neuronal excitability, whereas progestins are inhibitory (Halbreich, 2003a). Menstruation-related symptoms are believed to be associated with neuroactive progesterone metabolites. Of these, allopregnanolone is a potent modulator of GABA receptors, and its effects mirror those of low-dose benzodiazepines, barbiturates, and alcohol. These effects may include loss of impulse control, negative mood, and aggression or irritability (Bäckström, 2014). Wang and colleagues (1996) noted fluctuations in allopregnanolone across the various menstrual cycle phases. These changes were implicated with PMS symptom severity.

Second, evidence also supports a role for serotonergic system dysregulation in PMS pathophysiology. Decreased serotonergic activity has been noted in the luteal phase. Moreover, trials of serotonergic treatments show PMS symptom reduction (Marjoribanks, 2013).

Third, sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS) to alter electrolyte and fluid balance. The antimineralocorticoid properties of progesterone and possible estrogen activation of the RAAS system may explain PMS symptoms of bloating and weight gain.

The most recent agent implicated in PMDD is brain-derived neurotrophic factor (BDNF). Neurotrophins are involved in neuronal survival, synaptic signaling, and synaptic integration, and BDNF is considered one the most important. BDNF is modified by estradiol and demonstrates cyclic fluctuation across the menstrual cycle. In women with PMDD, levels of BDNF are

significantly higher during the luteal phase than in the follicular phase (Oral, 2015). Last, differences brain structure and function have been noted between women with and without PMDD in small imaging studies (Baller, 2013; Ossewaarde, 2013).

Diagnosis

PMDD is identified in the DSM-5 by the presence of at least five symptoms accompanied by significant psychosocial or functional impairment (Table 14-9). PMS refers to the presence of numerous symptoms that are not associated with significant impairment. During evaluation, the revised criteria in DSM-5 recommend that clinicians confirm symptoms by prospective patient mood charting for at least two menstrual cycles. In certain instances, complaints may be an exacerbation of an underlying primary psychiatric condition(s). Thus, other common psychiatric conditions such as depression and anxiety disorders are excluded. Additionally, other medical conditions that have a multisystem presentation are considered. These include hypothyroidism, systemic lupus erythematosus, endometriosis, anemia, fibromyalgia, chronic fatigue syndrome, fibrocystic breast disease, irritable bowel syndrome, and migraine.

TABLE 14-9. Diagnostic Criteria for Premenstrual Dysphoric Disorder

A. ≥5 symptoms below: occur in most cycles during the week before menses onset, improve within a few days after menses onset, and diminish in the week post-menses

B. One (or more) of the following symptoms must be present:
- Marked affective lability
- Marked irritability or anger or increased interpersonal conflicts
- Marked depressed moods, feelings of hopelessness, or self-deprecating thoughts
- Marked anxiety, tension

C. One (or more) of the following symptoms must be also present:
- Decreased interest
- Difficulty concentrating
- Easy fatigability, low energy
- Increase or decrease in sleep
- Feelings of being overwhelmed
- Physical symptoms such as breast tenderness, muscle or joint aches, "bloating" or weight gain

Note: Criteria A–C must be present for most menstrual cycles in the preceding year.

D. Symptoms are associated with significant distress or interferences with work, school, relationships

E. The disturbance is not merely an exacerbation of another disorder such as major depression, panic disorder, persistent depressive disorder, or a personality disorder.

F. Criterion A should be confirmed by prospective daily ratings in at least two symptomatic cycles.

G. The symptoms are not due to physiological effects of a substance or another medical condition.

Data from American Psychiatric Association, 2013.

Treatment

Therapy for PMDD and PMS includes psychotropic agents, ovulation suppression, and dietary modification. Generalists may consider treatment of cases with mild-to-moderate severity. However, if treatment fails or if symptoms are severe, then psychiatric referral may be indicated (Reid, 2018).

Selective serotonin-reuptake inhibitors (SSRIs) are considered primary therapy for psychologic symptoms of PMDD and PMS, and fluoxetine, sertraline, and paroxetine are Food and Drug Administration (FDA) approved for this indication (Table 14-10). Standard dosages are administered in either continuous or luteal-phase (14 days prior to expected menses) dosing regimens. Several well-controlled trials of SSRIs show these drugs to be efficacious and well tolerated (Shah, 2008). In addition, short-term use of anxiolytics such as alprazolam or buspirone offers added benefits to some women with prominent anxiety. However, in prescribing benzodiazepines, caution is taken in women with prior history of substance abuse (Nevatte, 2013).

Because gonadal hormonal dysregulation is implicated in the genesis of PMS symptoms, ovulation suppression is another option. Some data supports use of combination oral contraceptive (COC) pills in general for premenstrual mood symptoms. Moreover, in randomized trials, *Yasmin*, a COC containing the spironolactone-like progestin drospirenone, showed therapeutic benefits. It carries an FDA indication for PMDD treatment in women who desire contraception (Pearlstein, 2005; Yonkers, 2005). Alternatively, GnRH agonists are another means of ovulation suppression. These agents are infrequently selected due to their hypoestrogenic side effects and risks. If elected for PMDD and used longer than 6 months, add-back therapy, as discussed in Chapter 11 (p. 243), can potentially blunt these effects. Rarely, symptoms warrant bilateral oophorectomy, and a trial of GnRH agonists prior to surgery may be prudent to determine the potential efficacy of castration. Last, the synthetic androgen danazol also suppresses ovulation, but androgen-related acne and hair growth are usually poorly tolerated.

Of other possible agents, prostaglandin inhibitors such as ibuprofen and naproxen offer benefits through their anti-inflammatory effects and alleviate cramping and headaches associated with PMS (Table 11-1, p. 242). Diuretics such as combined hydrochlorothiazide and triamterene (Dyazide) and spironolactone (Aldactone) may be prescribed to alleviate fluid retention and leg edema. Monitoring for potential side effects such as orthostatic hypotension and hypokalemia is essential.

Diet, in particular foods and beverages high in sugar and caffeine, can aggravate premenstrual symptoms in some women. Calcium, 600 mg orally twice daily, has shown benefits. Theoretically, this corrects deficiency-related symptoms such as muscle cramps (Thys-Jacobs, 2000). Vitamins such as pyridoxine (vitamin B_6) and vitamin E may offer some relief. Pyridoxine is a cofactor to tryptophan hydroxylase, which is the key enzyme in serotonin synthesis (Wyatt, 1999). The recommended dose of pyridoxine

TABLE 14-10. List of Common Psychotropic Medications

Drug Class	Indication	Examples[a]	Brand Name	Commonly Reported Side Effects
Selective serotonin-reuptake inhibitors (SSRIs)	Depressive, anxiety, and premenstrual disorders	Fluoxetine Citalopram Escitalopram Sertraline Paroxetine Fluvoxamine	Prozac, Sarafem Celexa Lexapro Zoloft Paxil Luvox	Nausea, headache, insomnia, diarrhea, dry mouth, sexual dysfunction
Serotonin noradrenergic-reuptake inhibitors (SNRIs)	Depressive, anxiety, and premenstrual disorders	Venlafaxine XR Duloxetine Levomilnacipran Desvenlafaxine	Effexor Cymbalta Fetzima Pristiq	Dry mouth, anxiety, agitation, dizziness, somnolence, constipation
Tricyclic and tetracyclic antidepressants	Depressive and anxiety disorders	Desipramine Nortriptyline Amitriptyline Doxepin Maprotiline	Norpramin Pamelor, Aventyl Elavil Sinequan Ludiomil	Drowsiness, dry mouth, dizziness, blurred vision, confusion, constipation, urinary retention and frequency
Benzodiazepines	Anxiety disorders	Alprazolam Clonazepam Diazepam	Xanax Klonopin Valium	Drowsiness, ataxia, sleep changes, impaired memory, hypotension
Others	Depressive disorders	Nefazodone Trazodone Bupropion SR, XL Mirtazapine	Serzone Desyrel Wellbutrin Remeron	Headache, dry mouth, orthostatic hypotension, somnolence Dry mouth, increased appetite, somnolence, constipation
		Vilazodone Aripiprazole[a]	Viibryd Abilify	Diarrhea, nausea, dry mouth Weight gain, akathisia, extrapyramidal signs, somnolence
		Vortioxetine	Brintellix	Constipation, nausea, vomiting
	Anxiety disorders	Buspirone Hydroxyzine	Buspar Vistaril, Atarax	Dizziness, drowsiness, headache
	Sleep agents	Zaleplon Zolpidem Ramelteon Eszopiclone	Sonata Ambien, Intermezzo, Edluar, Zolpimist Rozerem Lunesta	Headache, somnolence, amnesia, fatigue

[a]Adjunctive treatment in patients receiving antidepressants.
SR = sustained release; XR/XL = extended release.

is 50 to 100 mg/d, but doses exceeding 100 mg/d are avoided to prevent pyridoxine toxicity. Magnesium in combination with vitamin B_6 appears to reduce anxiety-related premenstrual symptoms (De Souza, 2000). Of nonpharmacologic alternatives to treatment, acupuncture, bright-light therapy, exercise, and omega fatty acids have some evidence-based support (Brandon, 2014).

PERINATAL DISORDERS

In general, psychiatric disorders during pregnancy have a course and presentation similar to that in nonpregnant women. For this reason, there are no distinct diagnostic criteria for psychiatric disorders experienced in the context of pregnancy and the puerperium.

Perinatal Depression

In the revised DSM-5, a major depressive episode with onset during pregnancy or within 4 weeks following childbirth is categorized by a specifier term noting "with peripartum onset." Some women experience the first onset of depression during this time, whereas others are vulnerable for relapse (Cohen, 2006a). Etiologic studies have been inconclusive, but both hormonal changes and psychosocial stressors are implicated (Bloch, 2006; Boyce, 2005). Other risks include life stress, poor social support, and maternal anxiety (Lancaster, 2010).

Treatment is critical, as suicide is a leading cause of maternal death in developed countries (Centre for Maternal and Child Enquiries, 2011). Accordingly, health professionals are

encouraged to thoroughly assess psychiatric and psychosocial history to enable early identification, prevention, and treatment of perinatal depression. The American College of Obstetricians and Gynecologists (2018) recently advised obstetric care providers to screen perinatal women at least once during the perinatal period for depression and anxiety using a standardized, validated tool. Even if screening occurs during pregnancy, providers are also urged to complete a full assessment of emotional well-being during the postpartum visit.

To screen for and assess severity of peripartum depressive symptoms, the Edinburgh Postnatal Depression Scale (EPDS) is one tool specifically developed for pregnancy (Cox, 1987). Unlike screening measures that score symptoms characteristic of pregnancy itself (appetite, weight change, sleep disturbance, and fatigue), the EPDS assesses neurovegetative symptoms that are more specific to depression. Available in numerous languages, the EPDS is an efficient way to identify patients at risk for perinatal depression. It is available through the American Academy of Pediatrics at: www2.aap.org/sections/scan/practicingsafety/toolkit_resources/module2/epds.pdf.

Antepartum

From a global perspective, the pooled prevalence of perinatal depression is estimated to be 12 percent (Woody, 2017). Specific to pregnancy, depression has been estimated to be highest (11 percent) in the first trimester and falls to 8.5 percent in the second and third trimesters (Gaynes, 2005). For treatment, the American Psychiatric Association and American College of Obstetricians and Gynecologists issued pregnancy guidelines for depression management that recommend careful risk and benefit analysis of existing treatment (especially medications) (Yonkers, 2009). For major depression, psychotropic medication and psychotherapy have the largest evidence-based support (Stuart, 2014). However, data also note efficacy for several complementary interventions (Deligiannidis, 2014). The FDA (2006, 2011b) recommends careful and transparent risk assessment during pregnancy before prescribing psychotropic medications. The FDA (2014) has also eliminated the letter risk categories (A, B, C, D and X). Currently, the Pregnancy and Lactation Labeling Rule (PLLR) specifically highlights risks and benefits of the medication to mother and fetus and its benefit for the underlying illness. Additional guidance is found in *Williams Obstetrics*, 25th edition (Dashe, 2018). Nonpharmacologic and complementary approaches are also potential options for depressive symptoms during pregnancy. These include acupuncture, bright light therapy, exercise, omega fatty acid supplementation, and yoga and massage therapies (Field, 2012; Manber, 2010; Shivakumar, 2011; Su, 2008; Wirz-Justice, 2011). Electroconvulsive therapy (ECT) is reserved for those unresponsive to pharmacotherapy. In one review, ECT was 78-percent effective, but maternal and fetal complication rates were 5 and 3 percent, respectively (Andersen, 2009).

Postpartum

Depression after childbirth is largely divided into three categories: "postpartum blues," postpartum depression, and postpartum psychosis. The strongest predictors of postpartum depression include prior history of depression or anxiety, family history of psychiatric illness, poor marital relationship, limited social support, and stressful life events in the previous 12 months (Boyce, 2005; Sayil, 2007).

Postpartum blues describes a transient state of heightened emotional reactivity that can develop in up to 50 percent of women. The onset is 2 to 14 days after childbirth, and its duration is less than 2 weeks (Gaynes, 2005). Blues generally require no intervention. Rest and social support contribute significantly to remission. However, postpartum blues do constitute a significant risk factor for subsequent depression during the puerperium.

Postpartum depression, as noted, includes onset during pregnancy and within 4 weeks following delivery. However, in research and most clinical settings, any depression developing within 12 months following childbirth is considered to have postpartum onset (Sharma, 2014). With this definition, the prevalence of postpartum depression globally ranges from 12 to 26 percent (Gaynes, 2005; Shorey, 2018). Postpartum depression warrants careful assessment by a mental health professional, and treatment is initiated immediately to minimize impaired caregiving. Infants of depressed mothers exhibit cognitive, temperamental, and developmental differences compared with those of unaffected mothers (Kaplan, 2009; Newport, 2002). SSRIs are usually first-line agents, although fluoxetine use is discouraged due to relatively high concentrations in breast milk (Sie, 2012). Psychosocial interventions, especially interpersonal therapy and cognitive-behavioral therapy, are also effective in treating postpartum depression (Sockol, 2015, 2018). In refractory cases, two hospital-based treatments can be considered. ECT, mentioned earlier, may improve symptoms (Gressier, 2015; Rundgren, 2018). Brexanolone is an allopregnanolone analogue and administered by infusion over a 48-hour period. Plasma allopregnanolone levels rise in connection with progesterone throughout pregnancy, and after childbirth these concentrations decrease abruptly. In small randomized trials, the drug significantly reduced Hamilton Rating Scale for Depression scores compared with placebo (Kanes, 2017; Meltzer-Brody, 2018). It has been recently FDA-approved for treatment of postpartum depression and is undergoing further evaluation. Additionally, for both clinicians and patients, Postpartum Support International is an excellent resource and is found at www.postpartum.net.

Last, *postpartum psychosis* develops uncommonly in new mothers, and its onset is generally within 2 weeks of childbirth (Gaynes, 2005; VanderKruik, 2017). The risk for this severe form of depression is increased for women who have had prior mood disorders. Particularly, prior postpartum psychosis increases a woman's risk with subsequent deliveries by 30 to 50 percent (American Psychiatric Association, 2013). Evaluation and antipsychotic pharmacologic treatment is essential for these patients. Hospitalization is often indicated until the safety of mother and infant is assured.

Other Psychiatric Disorders

Clinicians most often focus on mood disorders during the perinatal period. However, anxiety disorders, bipolar disorders, schizophrenia, and others may also be present. Of these, bipolar disorders and schizophrenia are serious, recurrent psychiatric illnesses that require pharmacologic treatment. Treatment planning is critical with such patients, and decisions are made in collaboration with a psychiatric professional. The FDA (2011a)

issued a safety communication alerting health-care providers concerning some antipsychotic medications that are associated with neonatal extrapyramidal and withdrawal symptoms similar to the neonatal behavioral syndrome seen in those exposed to SSRIs. Thus, a careful balance must be struck between minimizing medication risk to the fetus and maternal risk from untreated or undertreated disease.

Perinatal Loss, Trauma, and Pregnancy Interruption

When pregnancy or childbirth has a tragic outcome, a clinician's actions and words affect a woman's memory of the event and her grieving process. Health-care providers are most helpful if they speak directly, use understandable language, and share information that would provide parents a sense of control over their situation and that would address their fears. Extra time with health professionals and a perception of being a priority are also important (DiMarco, 2001; Flenady, 2014). Since grief is individual, no generalizations can be made concerning clinical treatment in these situations. Thus, a provider must ask a patient what she needs and wants. Conjoint psychotherapy may be helpful if mother and father are struggling to communicate with each other about their emotional needs and experiences of grief. Psychologic treatment may also be necessary if symptoms of posttraumatic stress disorder (PTSD) emerge in the weeks after the birth or loss. Family therapy may be indicated if other children need support to process the loss and their parents' grief. Many hospitals have pregnancy loss support services, often managed by hospital chaplaincy. In addition, online resources for information and local support groups are www.pregnancyloss.info and www.missfoundation.org.

Pregnancy interruptions due to fetal anomalies that are incompatible with life outside the womb also require enhanced caregiver sensitivity. The term "interruption" may be more acceptable than "termination." Privacy within the patient's social support system is important to understand, given that some women are more comfortable describing the loss as a "miscarriage" or "stillbirth" rather than a termination.

MENOPAUSAL TRANSITION AND MENOPAUSE

The *menopausal transition* has long been investigated as a vulnerable period for emergence of mood symptoms. Anxiety, irritable mood, and sleep problems are more likely to develop in perimenopausal women than in premenopausal counterparts (Brandon, 2008; Freeman, 2006). Moreover, data suggest that rates of new-onset depression during menopause transition are nearly twice those for premenopausal women (Cohen, 2006b). This risk persists even after adjusting for sleep disturbances and vasomotor symptoms.

Other possible risks for depression and anxiety are a prior history of depression or severe premenstrual distress, hot flashes, and disrupted sleep. Demographic predictors of higher risk during the perimenopause are lower educational status, African-American ethnicity, unemployment, and major life stressors (Bromberger, 2001; Freeman, 2006; Maartens, 2002). Developmentally, many women are transitioning from being family focused to finding new avenues in which to invest time and energy.

Mood vulnerability during menopause transition is believed to follow fluctuations in reproductive hormones. Detailed discussion of these hormones as they relate to mood changes during this transition is found in Chapter 22 (p. 500).

Evaluation and Treatment

Perimenopausal women with psychologic symptoms warrant a comprehensive psychosocial inventory and risk factor assessment. Since medical conditions may concurrently develop during this transition, evaluation excludes these before symptoms are considered psychosomatic. In particular, thyroid function is evaluated.

The approach to treating mood symptoms involves both pharmacotherapy and psychotherapy (Brandon, 2008). Recommended psychotropic medications are SSRIs and selective noradrenergic-reuptake inhibitors (SNRIs) such as venlafaxine (Effexor). These agents are good options for women who decline hormone therapy. Additional benefits include alleviation of vasomotor symptoms and sleep disturbance. As discussed further in Chapter 22 (p. 485), SSRIs and SNRIs may also offer significant symptom relief for those without mood disorders (Cobin, 2017; Guthrie 2015; Maki, 2018).

Studies suggest that short-term administration of estrogen is an option for perimenopausal women with depressive symptoms (Soares, 2001). However, the psychotropic role of estrogen-progesterone preparations in postmenopausal women remains unclear. Moreover, benefits are weighed against safety concerns raised by the Women's Health Initiative (WHI) Study regarding estrogen use (Chap. 22, p. 479). Of nonpharmacologic alternatives investigated for mood disturbance during menopause, yoga and moderate-intensity exercise have demonstrated benefit (Brandon, 2014). However, these studies are small.

LATE LIFE

According to the United States Census Bureau (2018), by 2035, an estimated 78 million people will be 65 years or older, whereas an estimated 77 million will be younger than 18 years. For women in later life, psychosocial issues addressed are significantly different. Stressors may include diminished mental and physical function and loss of partner, family, or friends. Erikson identified the task of this final developmental stage of life as one of consolidation and integration. In this model, women retrospectively examine their life. They may manage their last years with integrity and with satisfaction in a life well lived, or may suffer despair, feeling that all was in vain.

The prevalence rates for psychiatric disorders in older adults are understudied and are so heterogeneous that confident application of data to older women is difficult. One recent review estimates combined male and female rates of depression to be 3.3 percent; of generalized anxiety disorder, 2.3 percent; and of alcohol use disorder, 1 percent (Volkert, 2013). One review looking at gender differences and depression reported prevalence rates of at least 8.4 percent in women aged 70 and older (Luppa, 2012). Importantly, psychiatric disorders do not

disappear in later life, and evaluation of older women should include considerations of mental health.

Evaluation and Treatment

If a psychiatric disorder is suspected, underlying medical causes for these changes are ideally excluded. For example, depression may be a comorbid disorder with or an early symptom of Alzheimer or Parkinson disease (Polidori, 2001). Alternatively, depression, anxiety, and psychosis may also result from a single medication or medication combinations.

Specific screening questionnaires for depression have been developed for the elderly, such as the Geriatric Depression Scale (Brink, 1982). This screening tool is available in various languages at: www.stanford.edu/~yesavage/GDS.html. In addition, neuropsychologic evaluation is helpful to discriminate between symptoms and cognitive impairment. Dementia screening is discussed in Chapter 1 (p. 18).

Recognizing the natural decline in serotonin levels with aging, many gerontologists prescribe SSRIs for their patients. However, communication among all treating physicians to coordinate medications and minimize interactions is particularly important.

Psychosocial treatments are often helpful for the patient and, where applicable, her caregivers. Cognitive-behavioral therapy and interpersonal therapy are both efficacious with the elderly. Moreover, family therapy can be of great value to those struggling with end-of-life issues, functional impairments, multiple losses, and caregiver burden. Social workers can often help identify additional care resources.

For depression in older adults, one metaanalysis of 89 studies found that pharmacotherapy or psychotherapy achieved comparable results. In contrast, for anxiety, another analysis of 32 studies found pharmacotherapy slightly more effective than psychotherapy (Pinquart, 2006, 2007). Thus, treatment planning is individualized and assesses patient preference, contraindications, and treatment access.

OVERVIEW OF SEXUAL HEALTH

Sexual health is an essential component of overall health and well-being. According to the World Health Organization, sexual health is defined as physical, psychologic, and sociocultural well-being related to sexuality. It reflects not only a lack of disease or dysfunction, but also the free, responsible expression of one's sexual capabilities that nurture social well-being. Sexual health requires that an individual's sexual rights be respected and that sexual experiences be safe and pleasurable, free of discrimination, violence, and coercion (World Health Organization, 2006).

Obstetric, gynecologic, and other primary care settings are a common first point of contact for patients with sexual health concerns (Gott, 2004). Unfortunately, women's sexual concerns often go unassessed. For example, patients may hesitate to initiate conversations regarding this topic (Marwick, 1999). And for clinicians, insufficient medical training can lead to a lack of confidence in their knowledge or ability to respond to a patient's sexual concerns (Kingsberg, 2006; Shindel, 2013; Solursh, 2003). Thus, an improved understanding of normal functioning and female sexual dysfunction (FSD) would likely narrow this gap in clinical care.

FEMALE SEXUAL FUNCTIONING

Female Sexual Response

Female sexual functioning encompasses multiple aspects of the sexual response cycle including desire (sexual drive that can be spontaneous or responsive to sexual stimuli), arousal (sexual excitement or perception of sexual pleasure), lubrication (vaginal wetness), and orgasm (climax of sexual pleasure). FSD is characterized by a distressing impairment in a specific domain of sexual response.

The biopsychosocial model (Fig. 14-1), when applied to the female sexual response, reflects sexuality's dynamic nature and highlights its multiple variables (Althof, 2005; Kingsberg, 2015). This model underscores the importance of thorough assessment of these components and the potential benefit of a multidisciplinary approach.

Female Sexual Dysfunction

Prevalence estimates of FSD vary, in part, due to variations in definitions, assessment of distress, and changes in diagnostic criteria across time. In the largest FSD prevalence survey in the United States, symptoms considered distressing were measured. Approximately 10 percent of women reported low desire, 5 percent noted poor arousal, and 5 percent listed orgasm difficulties (Shifren, 2008). Pain/penetration disorders are estimated to affect 14 to 34 percent of younger women and 6.5 to 45 percent of older women (van Lankveld, 2010).

To classify FSD, the Diagnostic and Statistical Manual of Mental Health Disorders, fourth edition, text-revised (DSM-IV-TR) identified six categories (American Psychiatric Association, 2000). These were hypoactive sexual desire disorder (HSDD) (persistent lack of desire); sexual aversion disorder (persistent aversion to sexual activities); female sexual arousal disorder (FSAD) (persistent lack of lubrication-swelling in response to sexual excitement); female orgasmic disorder (persistent lack of orgasm

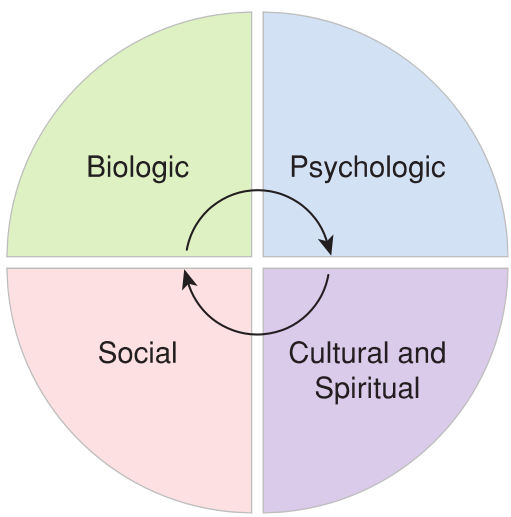

FIGURE 14-1 Biopsychosociocultural model.

following sexual excitement); dyspareunia (persistent genital pain with intercourse); and vaginismus (persistent involuntary muscle spasm in the outer third of the vagina with intercourse). FSD requires associated significant distress or impairment for diagnosis. Moreover, FSD symptoms are not better attributed to another disorder, medical condition, or effects of a substance.

The current DSM-5 describes three types of FSD (American Psychiatric Association, 2013). The first is female sexual interest/arousal disorder (FSIAD), which incorporates HSDD and FSAD. The other two are female orgasm disorder and genito-pelvic/pain or penetration disorder (GPPPD), which contains vaginismus and dyspareunia. The DSM-5 groupings remain controversial due to the combining of disorders and the lack of empirical support and validation of these combined disorders (DeRogatis, 2011; Pyke, 2015). In contrast, the International Consultation on Sexual Medicine (ICSM) Committee on Definitions and the International Society for the Study of Women's Sexual Health (ISSWSH) classifications align with the DSM-IV-TR (McCabe, 2016; Parish, 2016). The ICSM and ISSWSH recommend separation of desire and arousal disorders, noting benefits for assessment and treatment selection (Parish, 2016). Although treatment often is aimed toward addressing the primary problem, distress across more than one sexual function is common. Thus, an accurate assessment of sexual function is essential and helps to determine primary versus secondary components (Kingsberg, 2006).

ASSESSMENT OF SEXUAL FUNCTIONING

Brief Assessment

Providers can promote interactive discussion by establishing patient rapport and conveying comfort with the topic of female sexual health (Risen, 1995). Sitting rather than standing, relaxed but professional body language, and eye contact can increase patient ease. Moreover, knowledge and comfort with terminology can normalize the topic. Patients should be clothed, and the setting for discussion should be discreet.

A brief assessment of sexual concerns can be completed in 2 to 3 minutes using three components. First, the assessment is normalized and described as an important part of usual history taking. Questions then clarify if she is currently in a sexual relationship and determine the gender of partner(s). Third, specific patient concerns about sexual functioning are sought. For sexually inactive patients, issues that may be contributing to sexual inactivity are investigated (Kingsberg, 2006).

Complete Assessment

History

A complete reproductive health history can highlight components that may affect sexual response. Such information includes age at menarche, prior pregnancies or infertility, contraception use and type, and prior sexually transmitted disease. During a more systemic review, questions investigate prior gynecologic surgeries; urinary tract disease; endocrine disorders that involve sex steroid hormones, thyroid hormones, or diabetes; neurologic disorders; and cardiovascular diseases (Basson, 2000).

Many psychiatric conditions and their treatments can also negatively affect sexual response. These include mood and anxiety disorders, PTSD, substance abuse, eating disorders, and somatic symptom disorders (Atlantis, 2012; Laurent, 2009; Palha, 2008; Pinheiro, 2010; Solmaz, 2016; Yehuda, 2015). As examples, depression may decrease sexual desire and performance anxiety can affect vaginal muscle tension, creating pain or vaginismus. Other effects may stem from psychopharmacotherapy such as antiepileptics, antipsychotics, benzodiazepines, SSRIs, SNRIs, tricyclic antidepressants, and monoamine oxidase inhibitors (Basson, 2007; Kingsberg, 2007).

Partner-related variables may impair sexual functioning. The quality of the relationship, a partner's sexual functioning, and a partner's mental distress during sexual activity, such as performance anxiety, are examples. For individuals who identify as lesbian, gay, bisexual, transgender, fluid, or queer/questioning (LGBTQ), clinicians ideally are aware of specific sexual health risks and needs. Last, prior sexual victimization or physical abuse raises the risk of FSD (Luftey, 2008; Weaver, 2009).

Self-Report Measures

Validated self-report measures that assess female sexual response may help identify and qualify sexual functioning (Kingsberg, 2017). Common examples include the Female Sexual Function Index (FSFI) and the Sexual Function Questionnaire (SFQ), which both assess a range of sexual function domains. The Female Sexual Distress Scale (FSDS) assesses distress associated with impaired sexual response (DeRogatis, 2002; Quirk, 2002; Rosen, 2000). However, these measures are more commonly used in clinical research, and short screeners may be more useful in clinical settings. A single-item screener can be particularly time-efficient, and the Decreased Sexual Desire Screener (DSDS) is a five-item screener for acquired HSDD (Table 14-11) (Clayton, 2009; Flynn, 2015).

Physical Examination

To further assess physiologic components, examination may involve inspection of external genitalia and bimanual and speculum examinations (Phillips, 1998). In those with vulvodynia, significant findings and examination steps are outlined in Chapter 4 (p. 104). For those with dyspareunia, evaluation components are described in Chapter 12 (p. 266). For postmenopausal women, who may suffer from genitourinary syndrome of menopause (GSM), classic findings and treatment options are explained in Chapter 22 (p. 495).

Laboratory testing may aid diagnosis and treatment. Diagnostically, testing can help identify thyroid dysfunction, sex steroid hormone imbalance, and glucose abnormalities, which all can impair sexual function. Notably, some FSD treatments can adversely alter lipid and liver function values, and these are often assessed prior to drug initiation (Hatzichristou, 2004; Pauls, 2005).

TREATMENT

A stepped-care approach to sexual counseling allows for identification of sexual concerns and for appropriate referral. One

TABLE 14-11. The Decreased Sexual Desire Screener (DSDS)

Patient:

1. In the past was your level of sexual desire or interest good and satisfying to you? Yes/No
2. Has there been a decrease in your level of sexual desire or interest? Yes/No
3. Are you bothered by your decreased level of sexual desire or interest? Yes/No
4. Would you like your level of sexual desire or interest to increase? Yes/No
5. Please check all factors that you feel may be contributing to your current decrease in sexual desire or interest:
   - A. An operation, depression, injuries, or other medical condition
   - B. Medication, drugs or alcohol you are currently taking
   - C. Pregnancy, recent childbirth, menopausal symptoms
   - D. Other sexual issues you may be having (pain, decreased arousal or orgasm)
   - E. Your partner's sexual problems
   - F. Dissatisfaction with your relationship or partner
   - G. Stress or fatigue

Clinician:

If the patient answers "No" to any of the questions 1 through 4, she does not qualify for a diagnosis of hypoactive sexual desire disorder (HSDD).

If she answers "Yes" to all of questions 1 through 4 and "No" to all in question 5, she does qualify for a diagnosis of HSDD.

If she answers "Yes" to all of questions 1 through 4 and "Yes" to any in question 5, decide if the answers to question 5 indicate a primary diagnosis other than HSDD. A comorbid arousal or orgasmic disorder does not exclude concurrent HSDD.

From Clayton, 2009, with permission.

example is the PLISSIT model (Annon, 1976). With it, permission (P) to discuss sexual function is first requested. Next, limited information (LI) such as genital anatomy education is provided. Last, if indicated, specific suggestions (SS) to address the concern and subsequent intensive therapy (IT) by a trained therapist are offered. This model can be implemented according to the level of training a provider has received in this area. ISSWSH has published a similar algorithm for process of care for identifying and treating HSDD (Clayton, 2018). The treatment overview presented next is artificially separated into pharmacologic and psychosocial approaches. However, given the biopsychosocial model of FSD, an interdisciplinary treatment approach may be required.

Pharmacologic Treatments

Neuroendocrine functions are essential to sexual response. Excitatory neurochemicals are dopamine, oxytocin, norepinephrine, and melanocortin. Inhibitory ones include serotonin, opiates, and endocannabinoids (Burnett, 2010; Kingsberg, 2015, 2017). As such, overactive inhibition or underactive excitatory mechanisms or both may contribute to lowered sexual response. Sex steroid hormones modulate response to internal and external sexual stimuli. All these factors may serve as targets for both nonhormonal and hormonal intervention (Kingsberg, 2017).

Hypoactive Sexual Desire Disorder

Flibanserin. Treatments for HSDD include nonhormonal CNS medications. Flibanserin (Addyi) is a multifunctional 5-HT_{1A}-receptor agonist and 5-HT_{2A}-receptor antagonist. It normalizes excitatory and inhibitory neurotransmitter levels to enhance desire. Specific central actions lower serotonin and raise dopamine and norepinephrine activities (DeRogatis, 2012; Jayne, 2012; Katz, 2013; Thorp, 2012). Currently, it is the only FDA-approved medication to treat HSDD and is approved for premenopausal women (Goldstein, 2017). Although clinical trials demonstrate efficacy within 4 weeks, 8 to 12 weeks may be required for effect.

Side effects include dizziness and sleepiness, which is countered in part by bedtime administration. Because of a risk for hypotension and syncope when combined with alcohol, prescribers are required to complete a risk evaluation and mitigation strategy (REMS) program prior to prescribing Addyi (Sprout Pharmaceuticals, 2016). Although clinical trials have demonstrated safety and efficacy in postmenopausal women, flibanserin is not FDA approved for use in this population (Portman, 2017; Simon, 2013).

Off-Label Treatments. Of other agents, off-label use of bupropion, an antidepressant that is a norepinephrine- and dopamine-reuptake inhibitor, may increase sexual excitation and improve desire (Goldstein, 2017; Segraves, 2004). The anxiolytic buspirone is a partial 5-HT_{1A}-receptor agonist and presynaptic dopamine-receptor antagonist that can also improve desire (Clayton, 2014; Goldstein, 2017). Last, bremelanotide is a synthetic melanocortin analogue of α-melanocyte-stimulating hormone. Melanocortins are neuropeptides that modulate sexual behavior at the level of the hypothalamus and may translate sexual cues into genital response (Pfaus, 2007). In randomized trials in premenopausal women, bremelanotide improved desire and was well-tolerated (Clayton, 2016, 2018; DeRogatis, 2014; Portman, 2014). Although not currently

marketed, bremelanotide is under review by the FDA for approval.

Of hormonal treatment options, large randomized trials support the efficacy of exogenous testosterone (Achilli, 2017). Testosterone influences the synthesis and storage of neurotransmitters and can improve sexual response (Goldstein, 2017; Perelman, 2007). In several RCTs, the testosterone transdermal patch (Intrinsa) demonstrated safety and efficacy for the treatment of HSDD in postmenopausal women whether they were taking estrogen therapy or not (Braunstein, 2005; Buster, 2005; Davis, 2008). However, this patch was never FDA approved and is no longer marketed in Europe.

Currently, no FDA-approved testosterone option is available for women. Therefore, off-label testosterone products in women require careful monitoring for acne or hirsutism. These side effects may stem from inconsistent dosing while titrating male products or from compounding testosterone products. In addition, data on long-term effects on breast cancer rates and cardiovascular health remain limited. Thus, if testosterone use is planned, lipid and liver function are assessed prior to initiation, and breast cancer screening is performed as described in Chapter 13 (p. 293) (Shifren, 2015).

Phase II trials indicate promise for two combination pharmacotherapies—Lybrido and Lybridos (Tuiten, 2018). These are taken as needed, and they target hyperactive inhibitory and hypoactive excitatory responses or both to improve desire (Poels, 2013; van Rooij, 2013). Lybrido is a sublingual combination of testosterone and sildenafil, which is a phosphodiesterase type 5 inhibitor (PDE5i). Lybridos is a sublingual combination of testosterone and buspirone.

Combination oral contraceptives contain a progestin, and each progestin varies in its androgenicity (Chap. 5, p. 122). Although intuitively attractive, switching COC brands to one containing a more androgenic progestin has proven largely ineffective (Davis, 2013; Wallwiener, 2010).

Systemic estrogen therapy for postmenopausal women is not typically indicated for FSD. However, local hormone therapies are helpful for the treatment of GSM-related dyspareunia. Options discussed in Chapter 22 include estrogen cream, tablets, soft-gel caps, and rings; vaginal dehydroepiandrosterone; or oral ospemifene, which is a selective estrogen-receptor modulator (SERM) (North American Menopause Society, 2017).

Female Sexual Arousal Disorder

Hormonal treatment options for FSAD with some research support include testosterone therapy, just described (Davis, 2012; Laan, 2001; Tuiten, 2002). Another is tibolone, which is a SERM (Nappi, 2015).

Of nonhormonal treatments for FSAD, bupropion, described earlier, is an option (Levin, 2014; Maravilla, 2008). Sildenafil is a PDE5i hypothesized to improve sexual function due to enhanced genital blood flow (Caruso, 2006). Evidence for sildenafil efficacy in a general premenopausal female population is conflicting. But, in specific medical populations with genital neurovascular substrate interference, for example, spinal cord injury, subjective and objective parameters of sexual response are improved (Schoen, 2009).

Pain Disorders

Several pharmacologic agents have been used to treat female sexual pain disorders. However, few randomized trials have assessed their efficacy. Treatment may include nonhormonal options such as topical lidocaine ointment, topical hormonal cream, or antidepressants. In women with vestibulodynia secondary to oral contraceptive use, application of a topical compounded preparation containing 0.03-percent estradiol and 0.01-percent testosterone to the vestibule twice daily may be helpful (Burrows, 2013).

Pelvic floor physical therapy is a widely accepted treatment for sexual pain. Various techniques incorporate breathing/relaxation training, education, local tissue desensitization, electromyographic biofeedback, manual therapy, and a graded use of vaginal dilators. However, few randomized trials demonstrate efficacy for specific physical therapy protocols (Bergeron, 2010, 2015).

Last, some data support vestibulectomy for treatment of vulvodynia in the well-selected woman. But, complication rates preclude its use as a first-line treatment (Stockdale, 2014). Fuller discussions of vulvovaginal and pelvic pain disorders and their treatment are found in Chapter 4 (p. 104) and 12 (p. 266), respectively.

Psychologic Treatments

Several empirically supported psychologic interventions are available to treat FSD (Kingsberg, 2017; ter Kuile, 2010). Evidence indicates they can also affect neuroplasticity and functional brain mechanisms that drive sexual response (Goldstein, 2017).

For HSDD, research provides limited support for sex therapy, cognitive-behavioral therapy (CBT), and mindfulness techniques combined with CBT (Althof, 2011; Bradford, 2014; Brotto, 2014; Nobre, 2008). Sex therapy includes psychoeducation regarding sexual functioning. Techniques include counseling and sensate focused exercises, which are a graded series of sensual touching exercises starting with nongenital touch (Althof, 2011). CBT includes psychoeducation and focuses on altering maladaptive sexual cognitions, such as unrealistic negative thoughts about sexual activity, and maladaptive behaviors, such as avoiding sexual contact (Nobre, 2008). Mindfulness-based approaches, used with CBT, enhance one's ability to be in the present moment and emphasize a nonjudgmental awareness of sexual sensation and function. Also, for FSAD, mindfulness-based techniques with CBT have some research support (Brotto, 2014).

For orgasm disorder, directed masturbation can be helpful (Andersen, 1981; McMullen, 1979; Riley, 1978). This progressive series of exercises involves self-exploration of one's body and genitals. An awareness of sexual stimulation and response is designed to achieve self-stimulated orgasm and, later, potentially partner-stimulated orgasm (Heiman, 1988).

For pain disorders, limited data support CBT, therapist-aided exposure therapy, and mindfulness-based CBT for sexual pain (Brotto, 2015; Masheb, 2009; ter Kuile, 2013). Bergeron and associates (2015) offer a review of the topic. Therapist-aided exposure therapy includes psychoeducation regarding

female anatomy and function. Another component is guided, in vivo exposure exercises. During this, the patient has graded exposure to penetration by a dilator.

Pediatric gynecology is a unique subspecialty that encompasses knowledge from various specialties including general pediatrics, gynecology, and reproductive endocrinology, as well as pediatric endocrinology and pediatric urology. Treatment of a particular patient may thus require the collaboration of clinicians from one or more of these fields. In 1986, the North American Society for Pediatric and Adolescent Gynecology (NASPAG) was established to conduct and encourage medical education and research in the field of pediatric and adolescent gynecology (PAG). To further this mission, PAG fellowships are now available nationwide.

Gynecologic disorders in children can differ greatly from those encountered in the adult female. Even the simple physical examination of the genitalia differs significantly. A thorough understanding of these differences can aid in diagnosis.

PHYSIOLOGY AND ANATOMY

Hypothalamic-Pituitary-Ovarian Axis

A carefully orchestrated cascade of events unfolds in the neuroendocrine system and regulates development of the female reproductive system. In utero, gonadotropin-releasing hormone (GnRH) neurons develop in the olfactory placode. These neurons migrate through the forebrain to the arcuate nucleus of the hypothalamus by 11 weeks' gestation (Fig. 17-5, p. 378). They form axons that extend to the median eminence and to the capillary plexus of the pituitary portal system (Fig. 16-9, p. 344). GnRH, a decapeptide, is influenced by higher cortical centers and is released from these neurons in a pulsatile fashion into the pituitary portal plexus. As a result, by midgestation, the GnRH "pulse generator" stimulates secretion of gonadotropins from the anterior pituitary. The gonadotropins are follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In turn, the pulsatile release of gonadotropins stimulates ovarian synthesis and release of sex steroid hormones. Concurrently, accelerated germ cell division and follicular development begins, resulting in the creation of 6 to 7 million oocytes by 5 months' gestation. By late gestation, sex steroids exert a negative feedback on secretion of both hypothalamic GnRH and pituitary gonadotropins. During this time, oocyte numbers decline through a process of gene-related apoptosis to reach a level of 1 to 2 million by birth (Vaskivuo, 2001).

At birth, FSH and LH concentrations rise abruptly in response to the fall in placental estrogen levels. Levels of these gonadotropins are highest in the first 3 months of life (Fig. 15-1). This transient rise in their levels is followed by an increase in sex steroid concentrations. This rise is thought to explain instances of neonatal breast budding, minor bleeding from endometrial shedding, short-lived ovarian cysts, and transient white vaginal mucous discharge. Following these initial months, gonadotropin levels gradually decline to reach prepubertal levels by age 1 to 2 years.

The childhood years are thus characterized by low plasma levels of FSH, LH, and estradiol. Estradiol levels typically measure <10 pg/mL, and LH values are <0.3 mIU/mL. Both may be assessed if precocious development is suspected (Neely, 1995; Resende, 2007). During childhood, ovaries undergo active follicular growth and oocyte atresia. As a result of this attrition, by puberty, only approximately 300,000 oocytes remain (Baker, 1963).

Anatomy

Pelvic anatomy also changes during early childhood. In the neonate, sonographically, the uterus measures approximately 3.5 to 4 cm in length and 1.5 cm in width. Because the cervix is larger than the fundus, the neonatal uterus is typically spade-shaped (Fig. 15-2) (Kaplan, 2016; Nussbaum, 1986). An echogenic central endometrial stripe is common and reflects the transiently elevated sex steroid levels described earlier. Fluid is seen within the endometrial cavity in 25 percent of female

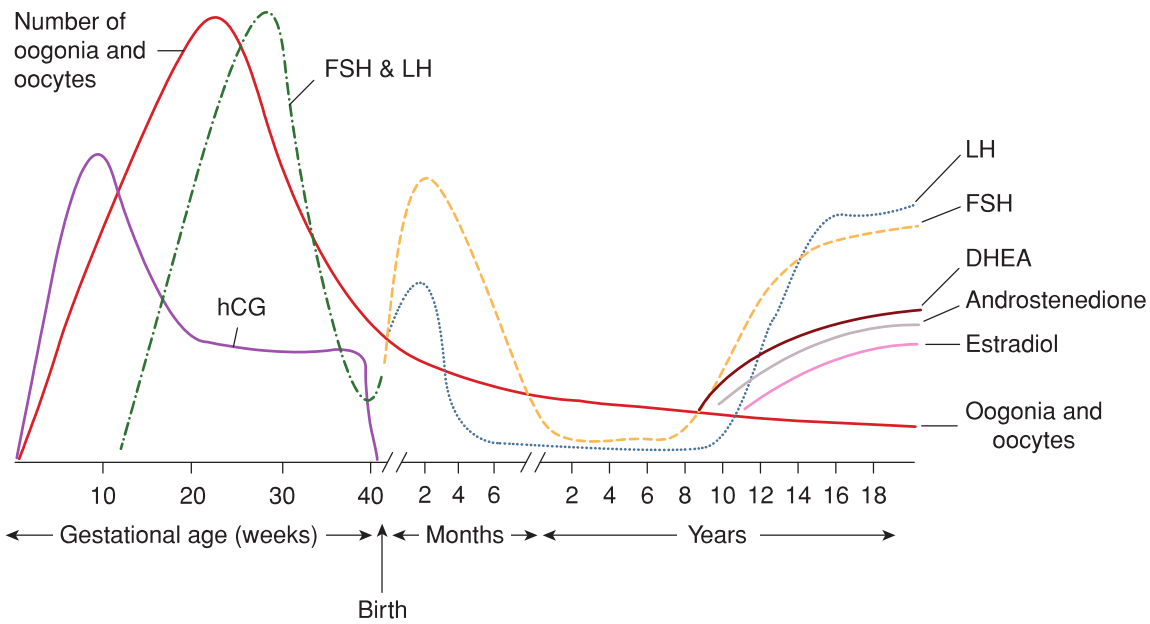

FIGURE 15-1 Variation in oocyte number and hormone levels during prenatal and postnatal periods. DHEA = dehydroepiandrosterone; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone. (Adapted with permission from Fritz, 2011.)

newborns. Ovarian volume measures ≤1 cm^3, and small cysts are frequently found (Cohen, 1993; Kaplan, 2016).

During childhood, the uterus measures 3 to 4 cm and is tubular as a result of the cervix and fundus becoming equal size. The ovaries grow in size as childhood progresses, and volumes range from 0.5 to 2 cm^3 (Buzi, 1998; Herter, 2002).

Pubertal Changes

Puberty marks the normal physiologic transition from childhood to sexual and reproductive maturity. With puberty, the hypothalamus, pituitary, and ovaries initially undergo an intricate maturation process. This maturation leads to a limited acceleration in body growth and to a complex development of secondary sexual characteristics involving the breast, sexual hair, and genitalia. Each landmark of hormonal and anatomic change during this time represents a spectrum of what is considered "normal."

Marshall and Tanner (1969) recorded breast and pubic hair development in schoolgirls and created the *Tanner stages* to describe pubertal development (Fig. 15-3). Initial pubertal changes begin between ages 8 and 13 years in most North American females (Tanner, 1985). Changes before or after are categorized as either precocious puberty or delayed puberty and warrant evaluation. In most girls, breast budding, termed

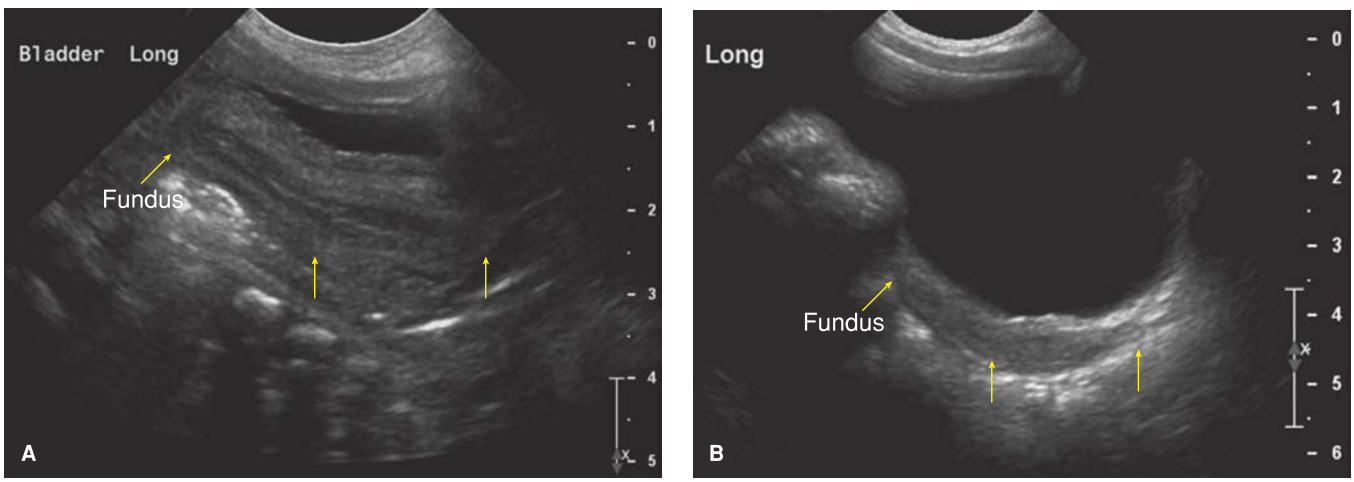

FIGURE 15-2 Transabdominal pelvic sonograms. **A.** Normal neonatal uterus. Midline longitudinal sonogram of the pelvis in this 3-day-old newborn demonstrates the uterus posterior to the bladder. Yellow arrows mark the fundus, isthmus, and cervix, respectively. The anteroposterior (AP) diameter of the cervix is greater than that of the fundus and creates a spade-shaped uterus. Due to the effect of maternal and placental hormones, a central echogenic endometrial cavity stripe is clearly visible. **B.** Normal prepubertal uterus. Midline longitudinal sonogram of the pelvis in this 3-year-old girl demonstrates the uterus posterior to the bladder. Yellow arrows mark the fundus, isthmus, and cervix, respectively. The uterus is homogeneously hypoechoic. The AP diameter of the cervix is equal to that of the fundus, and this gives the uterus a tubular shape. (Reproduced with permission by Dr. Neil Fernandes.)

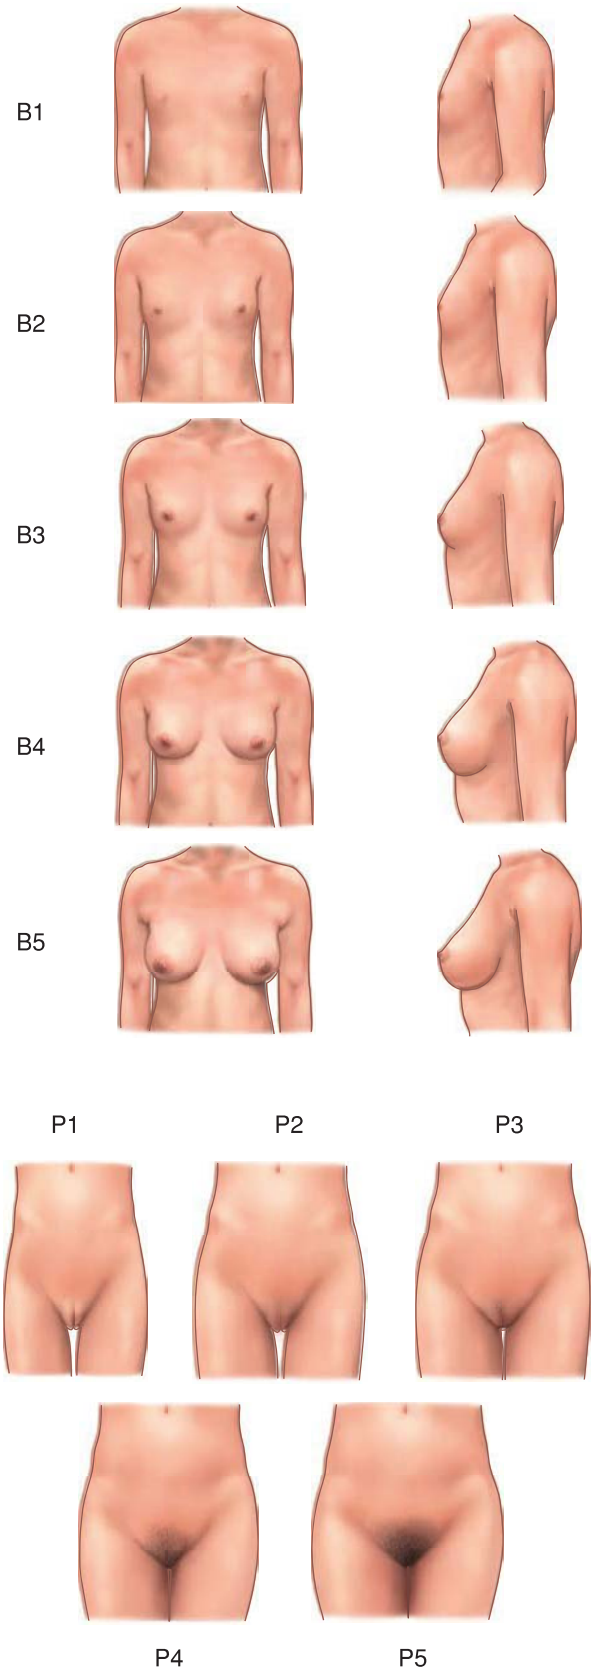

FIGURE 15-3 The Tanner stages of female breast and pubic hair development.

thelarche, is the first physical sign of puberty and begins at approximately age 10 (Aksglaede, 2009; Biro, 2006). In a minority, pubic hair growth, known as *pubarche*, develops first. Following breast and pubic hair growth, adolescents undergo an accelerated increase in height, termed a *growth spurt*, during a 3-year span from ages 10.5 to 13.5 years.

Since these original population studies, U.S. girls have trended to start thelarche and menarche earlier, although this trend has leveled off since the 1980s. Differences in onset timing are also related to race and higher body mass index (BMI) (Biro, 2013; Rosenfield, 2009). For example, higher BMI correlates with earlier pubertal development. The mean age of menarche in white girls is 12.7 years and is 6 months earlier, or 12.1 years, in black girls (Tanner, 1973).

GYNECOLOGIC EXAMINATION

An adolescent who has reached the age of 18 may consent to medical examination and treatment. Prior to this age, individual state laws govern whether minors can give their own consent for treatment of certain healthcare topics. Some examples include contraception, pregnancy care, substance abuse, mental health, and sexually transmitted diseases (STDs). Every state has laws allowing minors to consent to care if they are emancipated, living apart from their parents, or pregnant. The Guttmacher Institute (2018) and the Center for Adolescent Health & the Law offer resources (English, 2010).

A routine yearly examination of a child by her pediatrician generally includes a brief examination of the breasts and external genitalia. Congenital anomalies that are visible externally, such as imperforate hymen, may be identified. Alternatively, if parent or child has a specific complaint regarding vulvovaginal pain, rash, bleeding, discharge, or lesions, a gynecologic examination is directed toward the area of concern.

A parent or guardian should be present at the examination. This allows the child to understand that the examination is sanctioned. Moreover, clinicians can use this opportunity to inform a parent regarding findings and potential treatment. They can also emphasize the concept of inappropriate genital touching by others and parental notification if this occurs. In mid-to-late adolescence, however, a patient may prefer, for privacy reasons, not to be examined with a parent present.

"Child-friendly" objects or pictures and distracting conversation can ease fears and aid examination. Similarly, using an anatomically appropriate doll to explain the steps may decrease anxiety. The examination begins with a less-threatening approach of checking the ears, throat, heart, and lungs. Breasts are inspected. The external genital examination is best performed with the child in a frog-leg or knee-chest position to improve visualization. Occasionally, the patient may feel more comfortable sitting in a parent's lap. Sitting on a chair or examination table, the parent allows the child's legs to straddle the parent's thighs (Fig. 15-4).

Once the child is optimally positioned, each labium may be gently held with a thumb and forefinger and pulled toward the examiner and laterally. In this manner, the introitus, hymen, and lower portion of the vagina are inspected (Fig. 15-5). If a foreign body is suspected, vaginal irrigation can be performed in the office using a small feeding tube attached to a 60-mL

FIGURE 15-4 Various positions for examination of the pediatric patient (**A–D**).

FIGURE 15-5 **A.** Normal prepubertal genitalia. **B.** Imperforate hymen.

syringe of saline. This will often help expel small pieces of toilet paper that may have lodged behind the hymen.

An internal examination is rarely necessary unless a persistent foreign body, tumor, or vaginal bleeding is suspected. This evaluation is best accomplished under general anesthesia.

Vaginoscopy may be performed using a small-caliber hysteroscope or cystoscope that will fit the hymeneal aperture. Warm normal saline serves as the distending media. The labia majora are manually approximated, which occludes the vagina, traps the saline, and permits vaginal distention. The endoscope is withdrawn to within approximately 1 cm of the introitus for full visualization of the vagina (Fig. 15-6). Notably, in the unestrogenized prepubertal vagina, petechiae may form with vaginal distention.

LABIAL ADHESION

Adhesion between the labia minora begins as a small posterior midline fusion, which is usually asymptomatic. This fusion may remain an isolated minor finding or may progress toward the clitoris to completely close the vaginal orifice. Also termed *labial agglutination*, this adhesion develops in 1 to 5 percent

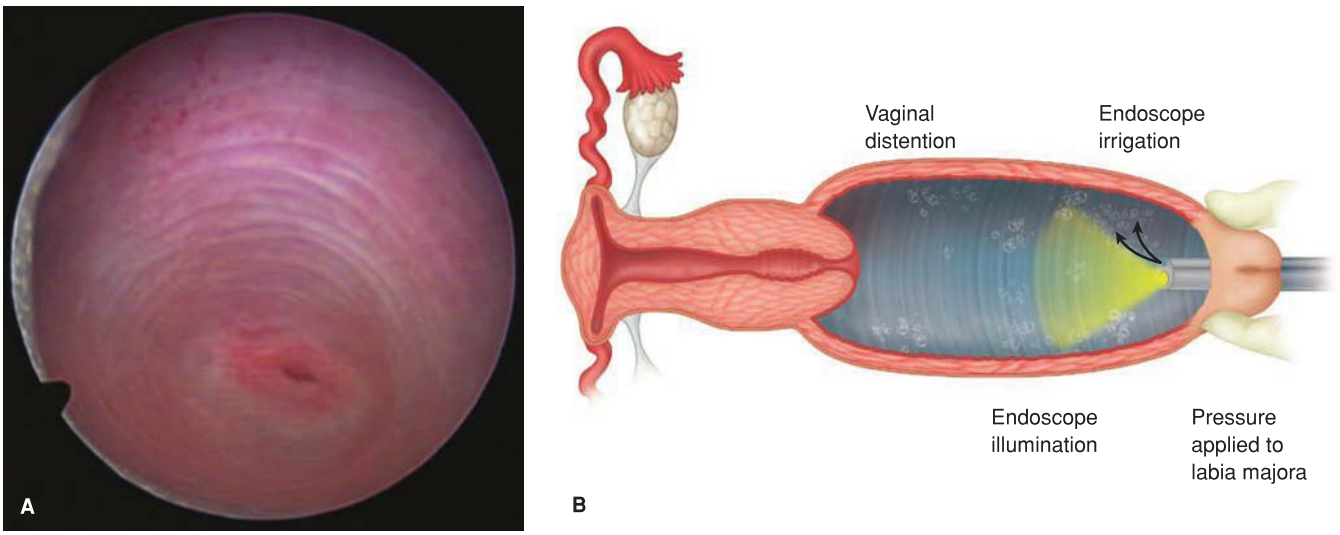

FIGURE 15-6 A. Photograph taken during vaginoscopy in an 8-year-old female. Typical for prepubertal girls, the cervix is almost flush with the proximal vagina. **B.** Drawing of vaginoscopy. The endoscope is first inserted toward the cervix to permit distention of the fornices. Next, the endoscope is retracted to within 1 cm of the hymen to allow global inspection of the vagina.

of prepubertal girls and in approximately 10 percent of female infants within the first year of life (Berenson, 1992; Christensen, 1971).

The cause of labial adhesion is unknown, although hypoestrogenism is implicated. This fusion typically develops in a low-estrogen environment. Namely, it is seen in infants and young girls and tends to undergo spontaneous resolution at puberty (Norris, 2018). Additionally, erosion of the vulvar epithelium is implicated in some cases of labial adhesion. For example, some cases of adhesion can be associated with lichen sclerosus, with herpes simplex viral (HSV) infection, and with vulvar trauma following sexual abuse.

The diagnosis is made visually. The labia majora appear normal, whereas the labia minora are fused with a distinct thin line of demarcation or *raphe* between them (Fig. 15-7). Extensive agglutination may leave only a ventral pinhole meatus between the labia. Located immediately beneath the clitoris, this small opening may lead to urinary dribbling as urine pools behind the adhesion. In these cases, urinary tract infection, urethritis, or vulvovaginitis can develop.

Treatment varies according to the degree of scarring and symptoms. In many instances, if the patient is asymptomatic, no intervention is necessary as the adhesion will typically resolve spontaneously with the rise of estrogen levels at puberty. Extensive adhesion with urinary symptoms, however, will require estrogen cream therapy. Estradiol (0.01 percent) cream (Estrace) or conjugated equine estrogen (Premarin) cream is applied to the fine, thin raphe twice daily for 2 weeks, followed by daily applications for an additional 2 to 4 weeks. A generous pea-sized amount of cream is placed with a finger or cotton-tipped applicator onto the raphe. With each application, gentle outward traction is exerted on the labia majora to help separate the adhesion. Similarly, light pressure may also be applied with the cotton applicator itself, as tolerated. After adhesion separation, a petroleum jelly (Vaseline) or vitamins A and D ointment (A&D ointment) may be applied nightly for 6 months to decrease the risk of recurrence. If the adhesion

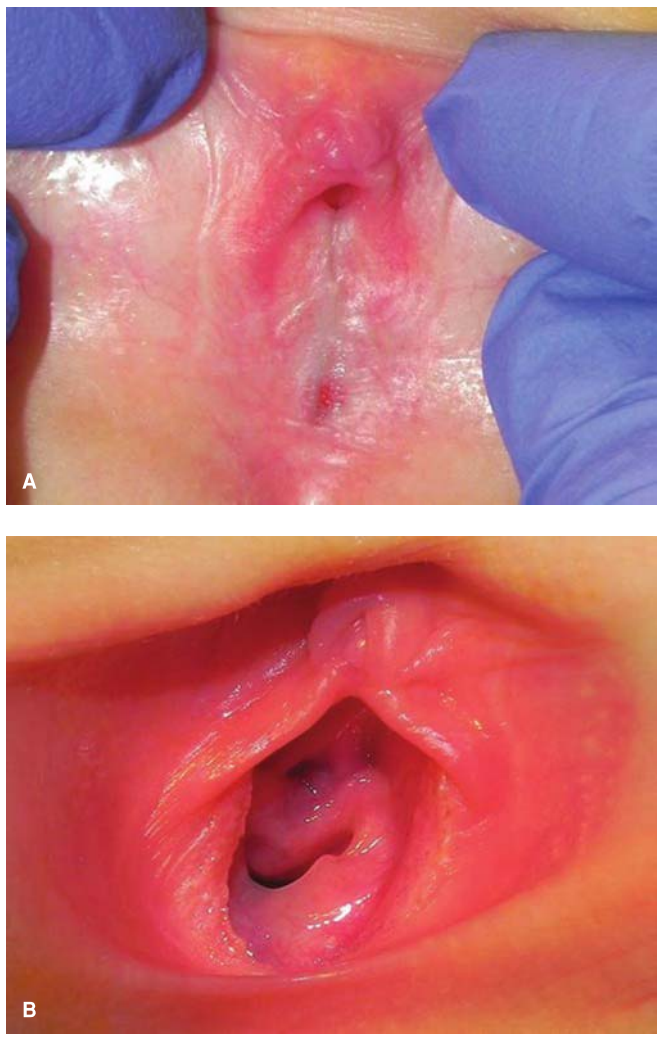

FIGURE 15-7 Labial adhesion. **A.** Labia minora are agglutinated in the midline. **B.** Resolution and restoration of normal anatomy.

reforms during the subsequent months or years, the process may be similarly repeated. Occasionally, with overuse of estrogen cream, local irritation, vulvar pigmentation, and minor breast budding may develop, at which time topical treatment is discontinued. These side effects are reversible once treatment is halted (Bacon, 2015). Alternatively, the use of 0.05-percent betamethasone cream applied twice daily for 4 to 6 weeks is another topical option (Mayoglou, 2009; Meyers, 2006).

For symptomatic patients, manual separation of labial adhesion in an outpatient setting without analgesia is painful and thus generally not advised. In addition, recurrence is much more common. However, if the adhesion persists despite consistent use of estrogen cream, then labia minora separation may be attempted several minutes after applying 5-percent lidocaine ointment to the adhesion raphe.

If manual separation is not easily accomplished or tolerated, surgical separation is best performed in an operating room under general anesthesia as an outpatient procedure. Midline division of the fused labia, also termed *introitoplasty*, uses an electrosurgical fine tip and does not require suturing.

To prevent repeated agglutination after manual separation or after surgery, an estrogen cream is applied nightly for 2 weeks. This is followed by an emollient cream nightly for at least 6 months.

CONGENITAL ANATOMIC ANOMALIES

Several anatomic and müllerian abnormalities present in early adolescence as obstructions to menstrual outflow. Described in Chapter 19, these include imperforate hymen, transverse vaginal septum, cervical and vaginal agenesis with an intact uterus, unicornuate uterus with an obstructed (noncommunicating) rudimentary horn, and the OHVIRA syndrome (obstructed hemivagina with ipsilateral renal agenesis) (Dietrich, 2014). These are often diagnosed in an adolescent with primary amenorrhea and cyclic pain. Notably, an adolescent with OHVIRA or with an obstructed rudimentary uterine horn will have menses, but these become increasingly painful over 6 to 9 months.

VULVITIS

Allergic and Contact Dermatitis

Vulvar inflammation may develop in isolation or in association with vaginitis. Allergic and contact dermatitis are common, whereas atopic dermatitis (eczema) and psoriasis are less frequent sources of itching and rash. With allergic and contact dermatitis the underlying pathophysiology varies, but the clinical appearance is usually similar. Vesicles or papules form on bright-red, edematous skin. However, in chronic cases, scaling, skin fissuring, and lichenification may be seen. In response, information regarding the degree of hygiene and continence and exposure to potential skin irritants is sought.

Typical offending agents include bubble baths and soaps, laundry detergents, fabric softeners and dryer sheets, bleach, and perfumed or colored toilet paper (Table 4-1, p. 93). Topical creams, lotions, and ointments used to soothe an area also may be an irritant to some children. For most, removing the offending agent and encouraging once- or twice-daily sitz baths is sufficient. These baths consist of placing two tablespoons of baking soda in warm water and soaking for 20 minutes. If itching is severe, an oral medication may be prescribed, such as hydroxyzine hydrochloride (Atarax) 2 mg/kg/d divided in four doses. Alternatively, a 2.5-percent topical hydrocortisone ointment can be applied twice daily for 1 week. Aside from chemical irritants, children can also develop diaper dermatitis from urine and stool exposure. Corrective measures aim to keep the skin dry by more frequent diaper changes or to create a moisture barrier by application of emollient creams, such as Vaseline or A&D ointment.

Lichen Sclerosus

Vulvitis may also be caused by lichen sclerosus, which has a premenarchal prevalence of 1 in 900 (Powell, 2001). With this, the vulva displays hypopigmentation; atrophic, parchment-like skin; and occasional fissuring. Lesions are usually symmetrical and may form an "hourglass" appearance around the vulva and perianal areas (Fig. 15-8). Occasionally, the vulva develops dark

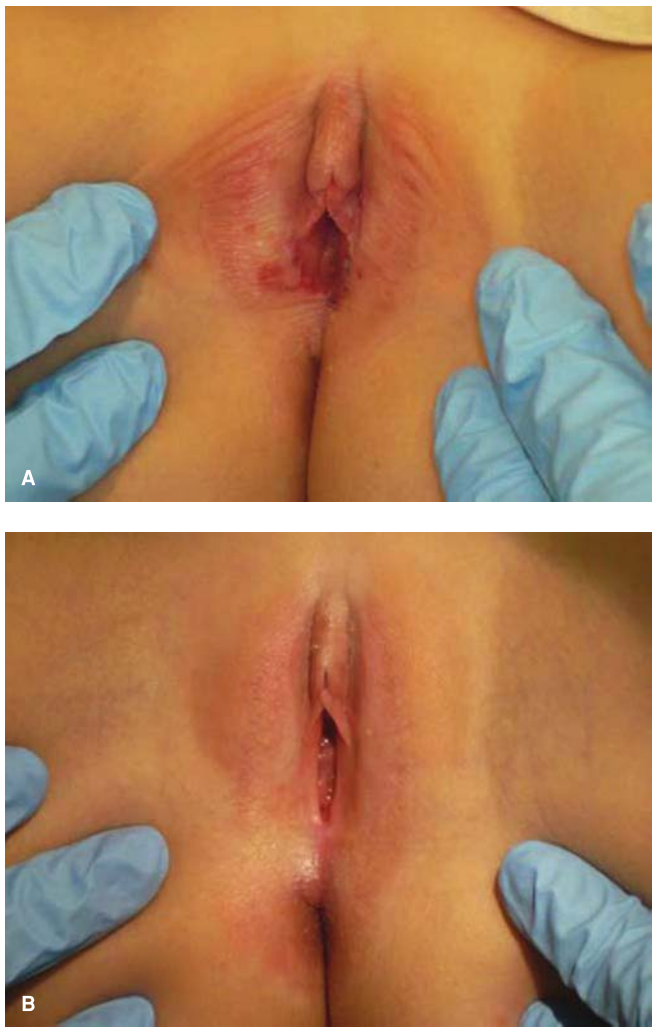

FIGURE 15-8 Lichen sclerosus before and after treatment. **A.** Findings include thin, parchment-like skin on the labia majora, ecchymoses on the labia minora and majora, and mild disease on the perianal skin. Involvement of both the vulva and perianal skin gives a figure-eight shape to affected areas. **B.** Skin texture and ecchymoses improved following treatment. (Reproduced with permission by Dr. Mary Jane Pearson.)

purple vulvar ecchymoses, which may bleed. Over time, if left untreated, the periclitoral area may scar, the labia minora may become attenuated, and the posterior fourchette may fissure and bleed.

Similar to labial adhesion, lichen sclerosus can develop concurrently with hypoestrogenism or with inflammation. Lichen sclerosus more commonly affects postmenopausal women and carries risks for vulvar malignancy. This association is not found in affected pediatric patients. The exact pathophysiology of lichen sclerosus is unknown, but a genetic susceptibility is implicated (Doulaveri, 2013; Sherman, 2010). An autoimmune process is also suspected given its association with Graves thyroiditis, vitiligo, and pernicious anemia (Meyrick Thomas, 1988). Patients may complain of intense itching, discomfort, bleeding, excoriations, and dysuria. Diagnosis typically relies on visual inspection. Rarely, a vulvar biopsy may be indicated in children if the classic skin changes are absent or if lesions are resistant to initial therapy (Bercaw-Pratt, 2014).

Treatment consists of proper hygiene and avoidance of irritants. For mild cases, topical corticosteroid ointment or cream such as 2.5-percent hydrocortisone is applied nightly to the vulva for 6 weeks. If improvement is noted, the dose may be lowered to 1-percent hydrocortisone and continued for 4 to 6 weeks. Thereafter, petroleum-based ointment use and strict attention to hygiene are recommended. Severe cases require a more potent corticosteroid such as 0.05-percent clobetasol propionate (Temovate), applied twice daily for 2 weeks. This initial dosing is followed by an individualized regimen, which slowly tapers the dose to a once-weekly bedtime application. Goals are resolution of skin atrophy, scarring, and symptoms.

The long-term prognosis for childhood lichen sclerosus is unclear. Although some cases resolve at puberty, small case series suggest that as many as 75 percent of affected children have disease that persists or recurs following puberty (Powell, 2002; Smith, 2009).

Infection

Some common infectious organisms that may cause prepubertal vulvitis include group A beta-hemolytic streptococcus, *Candida* species, and pinworms. With group A beta-hemolytic streptococcus, the vulva and introitus may be bright "beefy" red, and symptoms include dysuria, vulvar pain, pruritus, or bleeding. In most cases, vulvovaginal culture and clinical setting typically lead to diagnosis. Group A beta-hemolytic streptococcus is treated with an oral first-generation penicillin or cephalosporin or other appropriate antibiotic for 10 days.

Candidiasis is rare in prepubertal girls. It more often develops during the first year of life, after a course of antibiotics, or in females with juvenile diabetes or immunocompromise. A reddened, raised rash with well-demarcated borders and occasional satellite lesions is typical. Microscopic examination of a vaginal sample prepared with 10-percent potassium hydroxide (KOH) will help identify hyphae (Fig. 3-5, p. 64). For treatment, antifungal creams such as clotrimazole, miconazole, or butoconazole are applied to the vulva twice daily for 10 to 14 days or until the rash clears.

Enterobius vermicularis, also known as *pinworm*, can create intense vulvar itching. Nocturnal pruritus results from an intestinal infection with these 1-cm-long threadlike white worms that often exit the anus at night. Inspecting this area with a flashlight at night, parents may identify worms perianally. The "Scotch-tape test" entails pressing a piece of cellophane tape to the perianal area in the morning, affixing the tape to a slide, and visualizing parasite eggs by microscopy. Treatment is albendazole (Albenza) 200 to 400 mg in a single-dose chewable tablet.

VULVOVAGINITIS

Several months after birth, as estrogen levels wane, the vulvovaginal epithelium becomes thin and atrophic. As a result, the vulva and vagina are more susceptible to irritants and infections until puberty, and vulvovaginitis is a common prepubertal problem. Three fourths of vulvovaginitis cases in this age group are nonspecific, with culture results yielding "normal flora." Alternatively, several infectious agents, discussed subsequently, may be identified.

With *nonspecific vulvovaginitis*, the pathogenesis is not well defined, but known instigating factors are included in Table 15-1. Symptoms include itching, vulvar redness, discharge, dysuria, and odor. Most children and those adolescents who are not sexually active tolerate speculum examination poorly. But, a vaginal swab for bacterial culture can be comfortably obtained. In cases of nonspecific vulvovaginitis, cultures typically only isolate normal vaginal flora. Culture results that reveal bowel flora suggest contamination with fecal aerobes. Treatment attempts to correct the underlying cause. Itching and inflammation may be relieved with a low-dose topical corticosteroid ointment such as hydrocortisone, 1 or 2.5 percent. Occasionally, severe itching can lead to a secondary bacterial infection that requires oral antibiotics. Oral agents often selected are amoxicillin, an amoxicillin plus clavulanic acid combination, or a similar cephalosporin given during a 7- to 10-day course.

Infectious vulvovaginitis often presents with a malodorous, yellow or green purulent discharge, and vaginal cultures are routinely obtained in these cases. The respiratory pathogen group A beta-hemolytic streptococcus is the most common specific infectious agent found in prepubertal females. It is isolated from 7 to 20 percent of girls with vulvovaginitis (Pierce, 1992; Piippo, 2000). Treatment of group A beta-hemolytic streptococcus consists of amoxicillin, 40 mg/kg, taken orally three times daily

TABLE 15-1. Causes of Vulvovaginitis in Children

Poor vulvar hygiene
Short distance from the anus to the vagina
Inadequate front-to-back wiping after bowel movements
Lack of labial fat pads and labial hair
Nonestrogenized vulvovaginal epithelium
Vaginal foreign body
Chemical irritants such as soaps
Coexistent eczema or seborrhea
Chronic disease or altered immune status
Sexual abuse

FIGURE 15-9 Surgical excision of extensive vulvar condyloma in a prepubertal girl.

for 10 days. Less frequently, other respiratory pathogens found include *Haemophilus influenzae*, *Staphylococcus aureus*, and *Streptococcus pneumoniae* (Zuckerman, 2016). Enteric pathogens such as *Shigella* and *Yersinia* species also may be found by culture of vaginal discharge. Classically, *Shigella* species incite a mucopurulent bloody discharge, which typically follows diarrhea caused by the same organism. Treatment is with oral trimethoprim-sulfamethoxazole, 6 to 10 mg/kg/d, divided and given every 12 hours (Bogaerts, 1992).

Sexual abuse may lead to infections including those caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, HSV, *Trichomonas vaginalis*, and human papillomavirus (HPV). The clinical presentation of each mirrors the infectious findings in adults. Perinatal vertical transmission and latency may permit some of these to persist into infancy and childhood. Long latency and several possible modes of transmission render HPV especially difficult to assign origin (Fig. 15-9) (Unger, 2011). That said, child protective services are notified of any child suspected to be the victim of sexual abuse (Chap. 1, p. 23).

Vulvar aphthous ulcers, described in Chapter 4 (p. 100) cause marked pain. Vulvar mastocytosis and histiocytosis have been also described in prepubertal girls (Jorgensen, 2018; Lawson, 2018). Last, adolescents with inflammatory bowel disease may present with vulvar pain, ulcers, and edema prior to gastrointestinal symptoms (Debiec, 2018).

GENITAL TRAUMA

The prepubertal vulva is less protected from blunt injury due to the lack of labial fat pads. In addition, children are more physically active, thereby raising the trauma risk. Fortunately, most injuries to the vulva are blunt, minor, and accidental. Sharp-object penetration, however, may cause more serious injury to the vulvovaginal area. Sexual or physical abuse is also considered. Management of vulvovaginal trauma is discussed in greater detail in Chapter 4 (p. 107).

OVARIAN TUMORS

Ovarian masses, typically cysts, are common in childhood. They may be found prenatally during maternal sonographic evaluation or during prepubertal years and adolescence. Although most are benign, approximately 1 percent of all malignant tumors in this age group are ovarian (Breen, 1977, 1981).

Fetal and neonatal ovarian cysts are typically identified incidentally during antenatal sonographic examination. Although the true incidence of fetal ovarian cysts is not known, some cystic development has been reported in 30 to 70 percent of fetuses (Brandt, 1991; Lindeque, 1988). Most fetal cysts result from maternal hormonal stimulation in utero. Those during the neonatal period and infancy usually develop from the postnatal gonadotropin surge seen with the withdrawal of maternal hormones after birth. They are usually simple, unilateral, and asymptomatic, and they usually regress spontaneously by 4 months after birth, whether they are simple or complex. The risk of malignancy is low, although rupture, intracystic hemorrhage, visceral compression, and torsion followed by autoamputation of the ovary or adnexa may be complications.

For uncomplicated fetal or neonatal cysts measuring <5 cm in diameter, appropriate management is observation and sonographic examination every 4 to 6 weeks (Bagolan, 2002; Nussbaum, 1988). For simple cysts measuring ≥5 cm, antenatal or neonatal percutaneous cyst aspiration has been described to prevent torsion (Diguisto, 2018; Papic, 2014). Large complex ovarian cysts that do not regress postnatally require surgical excision.

In children, most ovarian masses are cystic and symptoms vary. Asymptomatic cysts may be discovered incidentally during abdominal examination or during sonographic evaluation for some other indication. Enlarging cysts can increase abdominal girth or cause chronic pain. Hormone-secreting cysts may lead to isosexual or heterosexual precocious puberty, and thus evaluation for signs of early pubertal development is indicated. Moreover, rupture, hemorrhage, or torsion may precipitate acute abdominal pain, similar to that seen in adults.

For imaging, a prepubertal child will not tolerate sonographic examination with a transvaginal probe. Thus, in this age group, transabdominal pelvic sonography is most frequently used. Sonographic qualities concerning for ovarian malignancy mirror those found in adults (Renaud, 2019). These are large size; thick, vascular septations; cyst wall excrescences; and mixed cystic with solid architecture (Chap. 10, p. 221). Computed tomography (CT) is helpful if a mature cystic teratoma (dermoid cyst) is suspected, as fat is better appreciated with this modality. Although magnetic resonance (MR) imaging is preferred for congenital müllerian anomaly evaluation, it is less helpful than pelvic sonography for ovarian mass determination.

The most common complex cysts found in childhood and adolescence are germ cell tumors, specifically benign mature cystic teratoma (Panteli, 2009). Rarely, tumors may be malignant germ cell tumors, which are the most common ovarian malignancy in this age group, or may be epithelial or sex cord–stromal ovarian tumors (Baert, 2016).

As with those of the fetal and neonatal periods, small simple ovarian cysts without thick septation or internal echoes may

be monitored with serial sonographic examination. Most less than 5 cm will resolve within 1 to 4 months (Thind, 1989). Persistent or enlarging cysts warrant surgery, and laparoscopy is preferred. Optimal management includes fertility-sparing ovarian cystectomy with preservation of normal ovarian tissue.

Following puberty, ovarian cysts in adolescents, as in adults, are frequent. Management mirrors that of adnexal masses found in adults as described in Chapter 10 (p. 219).

BREAST DEVELOPMENT AND DISEASE

Some newborns may have minor breast budding due to transplacental passage of maternal hormones in utero. Similarly, newborn breasts may produce *witches' milk*, which is a bilateral white nipple discharge, also a result of maternal hormone stimulation. Both effects are transient and diminish over several weeks to months.

At puberty, under the influence of ovarian hormones, the breast bud grows rapidly. The epithelial sprouts of the mammary gland branch further and become separated by increasing deposition of fat. Such breast development, termed *thelarche*, begins in most girls between the ages of 8 and 13 years. Thelarche prior to age 8 or lack of breast development by age 13 is considered abnormal and is investigated (p. 321).

Breast examination begins in the newborn period and extends through the prepubertal and adolescent years, as abnormalities can develop in any age group. Assessment includes inspection for accessory nipples, infection, lipoma, fibroadenoma, and premature thelarche.

Polythelia

Accessory nipples, also termed *polythelia*, are common and noted in 6 percent of patients (Göttlicher, 1986; Schmidt, 1998). Most frequently, a small areola and nipple are found along the embryonic milk line, which extends from the axilla to the mons pubis bilaterally. Accessory nipples are usually asymptomatic, and excision is not required. Rarely, however, they may contain glandular tissue that can lead to pain, nipple discharge, or development of fibroadenomas.

Breast Shape

Growth during early breast development in girls aged 13 to 14 years may be asymmetric. The etiology is not known. However, in some cases, sports injury or surgical trauma during early breast development may lead to asymmetry (van Aalst, 2009). Examination seeks to exclude a breast mass such as a fibroadenoma or cyst. If no mass is identified, then yearly breast examinations determine the extent and persistence of asymmetry. In most cases, asymmetry will resolve by the completion of breast maturity (Templeman, 2000). Therefore, a decision toward surgical intervention is not made until full breast growth is attained. Until that time, adolescents may be fitted with padded bras or even prosthetic inserts to ensure symmetry when fully clothed.

Extremely large breasts without concurrent large breast masses can rarely develop in adolescence. Such breast hypertrophy can incite back pain, shoulder discomfort from bra-strap pressure, kyphosis, and psychologic distress. These young women will often seek reduction mammoplasty, but surgery is delayed until age 18 years (American College of Obstetricians and Gynecologists, 2017a). Other elements of surgical timing include attainment of breast maturity and stability of bra cup size over 6 months.

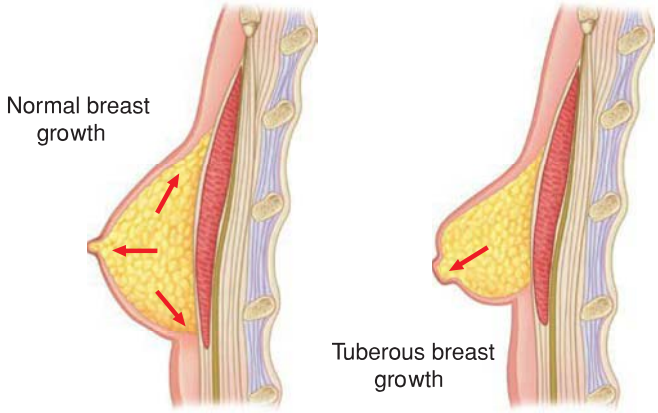

FIGURE 15-10 Comparison of normal and tuberous breast development.

Tuberous breasts are another growth variant (Fig. 15-10). With normal development, growth on the breast's ventral surface projects the areola forward, and circumferential peripheral growth enlarges the breast base. In some adolescents, the fascia is densely adhered to the underlying muscle and prohibits peripheral breast growth. Only forward breast growth is permitted, and *tuberous breasts* form (Grolleau, 1999). This appearance can also follow exogenous hormone replacement that may be prescribed to girls with a lack of breast development from genetic, metabolic, or endocrine conditions. To avoid tuberous development in this setting, hormone replacement is initiated at small dosages and gradually increased over time. For example, transdermal estrogen (estradiol patch), 0.025 mg, may be applied twice a week for 6 months, followed by incremental dose increases every 6 months, through doses 0.05 mg and 0.075 mg, to finally reach 0.1 mg twice a week. Medroxyprogesterone acetate (Provera), 10 mg, is given orally each day for 12 days of the month to prompt withdrawal periods. Once estrogen patch dosing has reached 0.1 mg daily, the patient may alternatively be placed on a low-dose oral contraceptive pill instead.

Absent Breast Development

Congenital absence of breast glandular tissue, termed *amastia*, is rare. More commonly, a lack of breast development results from low estrogen levels caused by constitutionally delayed puberty, chronic disease, Poland syndrome, radiation or chemotherapy, genetic disorders such as gonadal dysgenesis, or extremes of physical activity. Treatment is based on the etiology. For example, once a competitive athlete completes her career, breast development may begin spontaneously without hormonal treatment. In contrast, to prompt breast development and prevent osteoporosis, patients with gonadal dysgenesis will require some form of hormonal replacement, such as that described in the preceding section.

Breast Mass or Infection

Breast lump complaints in an adolescent often reflect fibrocystic changes. These are characterized by patchy or diffuse, bandlike thickenings. For discrete breast masses, sonography is selected to distinguish cystic from solid masses and to define cyst qualities (Kaneda, 2013). In contrast, mammography has a limited role. Its limited sensitivity and specificity in young, dense breast tissue yields high rates of false-negative results (Williams, 1986).

Actual breast cysts are found on occasion and will usually resolve spontaneously over a few weeks to months. If a cyst is large, persistent, or symptomatic, a fine-needle aspiration may be performed using local analgesia in an office setting.

Similarly, most breast masses in children and adolescents are benign and may include normal but asymmetric breast bud development, fibroadenoma, fibrocyst, lymph node, or abscess. The most common breast mass identified in adolescence is a fibroadenoma, which accounts for 80 to 90 percent of masses (McLaughlin, 2018; Sanders, 2018). Fortunately, breast cancer in pediatric populations is rare, and cancer complicates less than 1 percent of breast masses identified in this group (Gutierrez, 2008). Primary breast cancer may develop more frequently in pediatric patients with a history of prior radiation, especially treatment directed to the chest wall. Additionally, metastatic disease is a consideration in those with a known cancer.

Treatment of breast masses includes observation, needle biopsy, and surgical excision. Observation may be appropriate for small asymptomatic lesions considered to be fibroadenomas. Masses that are symptomatic, large, or enlarging are preferably excised, and techniques mirror those in the adult (Chap. 13, p. 280). For any mass not surgically excised, clinical surveillance is recommended to ensure mass stability.

Mastitis is rare in the pediatric population. Its incidence displays a bimodal distribution that peaks in the neonatal period and again in children older than 10 years. The etiology in these cases is unclear, but the association with breast enlargement during these two periods is implicated. *Staphylococcus aureus* is the most common isolate, and abscess develops more commonly than in the adult (Faden, 2005; Montague, 2013). In adolescents, infections may be associated with lactation and pregnancy, trauma from sexual foreplay, shaving periareolar hair, and nipple piercing (Templeman, 2000; Tweeten, 1998). Infections are treated with antibiotics to cover *S aureus* and occasional drainage if an abscess has formed.

VAGINAL BLEEDING

Neonates may present with vaginal bleeding during the first week of life due to the withdrawal of maternal hormones at birth. Bleeding typically resolves after a few days. Prepubertal bleeding in a child, however, merits careful evaluation (Table 15-2). Most instances of vaginal bleeding in these girls are due to local causes such as lichen sclerosis or urethral prolapse and can be elucidated with a simple history and physical examination. Foreign body is suspected when vaginal bleeding develops in children without signs of puberty or without local findings. Vaginal irrigation can be performed as described earlier (p. 322). Occasionally, an examination under anesthesia with saline vaginoscopy is required for diagnosis, particularly if a foreign body is present in the upper vagina (Fig. 15-11).

TABLE 15-2. Causes of Vaginal Bleeding in Children

PRECOCIOUS PUBERTY

Early pubertal development may be seen in both sexes, but females are much more commonly affected, with a sex ratio of 23:1 (Bridges, 1994). For girls, precocious puberty has historically been defined as breast or pubic hair development in those younger than 8 years. However, Herman-Giddens and colleagues (1997) noted that girls in the United States overall are undergoing normal pubertal development at younger ages than previously reported. In addition, racial differences exist. Puberty begins earliest in black girls, followed by Hispanic and white girls. Accordingly, to limit the proportion of girls requiring unneeded assessment for precocious puberty, some have suggested lowering the threshold age for evaluation (Herman-Giddens, 1997; Kaplowitz, 1999).

Premature pubertal development may result from various causes. These have been categorized based on pathogenesis and include central precocious puberty, peripheral precocious puberty, heterosexual precocious puberty, and temporal variation of normal puberty. Most girls evaluated are found to have normal pubertal development that has merely begun prior to standard temporal milestones and does not stem from identifiable

FIGURE 15-11 A clump of retained toilet paper was the foreign body found in this prepubertal girl.

pathology. However, because many of the underlying etiologies of precocious puberty carry significant sequelae, girls with early pubertal development are fully evaluated when identified.

Central Precocious Puberty (Gonadotropin Dependent)

Early activation of the hypothalamic-pituitary-ovarian axis leads to pulsatile GnRH secretion, increased gonadotropin production, and, in turn, higher sex steroid levels. Often termed *true precocious puberty* or *gonadotropin-dependent precocious puberty*, central precocious puberty is rare and affects 1 in 5000 to 10,000 individuals in the general population (Partsch, 2002). The most common cause of central precocious puberty is idiopathic, however, central nervous system lesions must be excluded (Table 15-3) (Muir, 2006; Nathan, 2005).

Symptoms of central precocious puberty are similar to those of normal puberty but at an earlier age. As outlined in Table 15-4, testing includes radiographic measurement of hand and wrist bone age. To explain bone age, as children develop, their bones change in size and shape. These changes can be seen radiographically and can be correlated with chronologic age. Thus, the radiographic "bone age" is the average age at which children in general reach a particular stage of bone maturation. Girls with early estrogen excess from precocious puberty show growth-rate acceleration, rapid bone-age advancement, and early epiphyseal closure, which leads to short stature. If the bone age is advanced by 2 or more years, puberty has begun and evaluation of precocious puberty is indicated. Also during evaluation, pelvic sonography is informative. Uterine length >3.5 cm indicates estrogen exposure, and multifollicular ovaries reflect central stimulation (Sultan, 2018). In addition, serum FSH, LH, and estradiol levels are elevated for chronologic age and typically lie in the pubertal range. Early in the process, however, FSH and LH levels may be elevated only in the evenings, and a leuprolide stimulation test can be diagnostically helpful.

During leuprolide stimulation, baseline FSH, LH, and estradiol levels are obtained. Leuprolide (Lupron), which is an initial GnRH agonist, is given as a single intravenous dose of 20 µg/kg and does not to exceed a total dose of 500 µg. FSH plus LH levels are measured at 1, 2, and 3 hours. An estradiol level is measured at 24 hours. Central precocious puberty is confirmed by a rise in serum LH levels following infusion of the GnRH agonist. In those with elevated gonadotropin levels, MR imaging of the central nervous system may identify a cerebral abnormality associated with central precocious puberty. In contrast, high estradiol levels and low gonadotropin levels during the stimulation test suggest peripheral precocious puberty, described subsequently.

Treatment goals focus on preventing short adult height and limiting the psychologic effects of early pubertal development. Epiphyseal fusion is an estrogen-dependent process. Thus, treatment consists of chronic GnRH agonist therapy with leuprolide. Although this agent acts as an initial stimulus to GnRH release, over time it desensitizes the GnRH receptor. This ultimately downregulates pituitary gonadotropes and in turn inhibits FSH and LH release. As a result, estrogen levels drop, and often breast and uterine sizes regress. If therapy is instituted after menses have begun, menstrual periods will cease. Timing for GnRH therapy discontinuation and reinitiation of pubertal

TABLE 15-3. Common Etiologies of Precocious Puberty

Central (GnRH-dependent)
Idiopathic[a]
CNS tumors
CNS anomaly
CNS infection
Head trauma
Ischemia
Iatrogenic: radiation, chemotherapy, surgical
Peripheral (GnRH-independent)
Estrogen- or testosterone-producing tumors (adrenal or ovarian)
Gonadotropin- or hCG-producing tumors
Congenital adrenal hyperplasia
Exogenous androgen or estrogen exposure
McCune-Albright syndrome
Ovarian follicular cysts
Primary hypothyroidism
Aromatase excess syndrome
Glucocorticoid resistance

[a]The most common cause of precocious puberty is idiopathic.
CNS = central nervous system; GnRH = gonadotropin-releasing hormone; hCG = human chorionic gonadotropin.

TABLE 15-4. Evaluation of Precocious Puberty[a]

development is determined by the primary therapy goals: maximizing height, synchronizing puberty with peers, and allaying psychological distress. From a review of several studies, the mean age at treatment discontinuation was approximately 11 years (Carel, 2009).

Peripheral Precocious Puberty (Gonadotropin Independent)

Less commonly, elevated estrogen levels may originate from a peripheral source, such as an ovarian cyst. Termed *peripheral precocious puberty* or *gonadotropin-independent precocious puberty*, this category is characterized by lack of GnRH pulsatile release and low levels of pituitary gonadotropins, yet elevated serum estrogen concentrations.

Although the originating source is variable, the most common cause is a granulosa cell tumor, which accounts for more than 60 percent of cases (Emans, 2005). Other types of ovarian cysts, adrenal disorders, iatrogenic disorders, and primary hypothyroidism are additional causes (see Table 15-3). McCune-Albright syndrome is characterized by a "triad" of polyostotic fibrous dysplasia, irregular café-au-lait spots, and endocrinopathies. Precocious puberty is a frequent finding and results from estrogen production in the ovarian cysts that are common in these girls.

Testing of girls with peripheral precocious puberty finds estrogen levels that are characteristically elevated, whereas serum levels of LH and FSH are low. Bone age determination shows advanced aging, and GnRH stimulation shows no elevation in serum LH levels. Pelvic sonography helps to identify ovarian cysts or tumors.

Treatment aims to eliminate excess estrogen. For those with exogenous exposure, halting the estrogen source, such as hormonal pills or creams, is sufficient. An estrogen-secreting ovarian or adrenal tumor will require surgical excision, and hypothyroidism is treated with thyroid hormone replacement.

Heterosexual Precocious Puberty

Androgen excess with signs of virilization is rare in childhood (Chap. 18, p. 397). Termed *heterosexual precocious puberty*, this condition is most commonly caused by increased androgen secretion in young females from the adrenal gland or ovary. Causes include androgen-secreting ovarian or adrenal tumors, congenital adrenal hyperplasia, Cushing syndrome, and exposure to exogenous androgens. Testing is outlined in Table 15-4. Treatment is directed at correction of the underlying etiology.

Variations of Normal Puberty

Although standardized age guidelines accurately reflect the timing of pubertal development in most girls, others begin development early. Premature thelarche, premature adrenarche, and premature menarche describe the premature pubertal development of breast tissue, pubic hair, and menses, respectively. Each develops in isolation and without other evidence of pubertal development.

Premature thelarche is a diagnosis of exclusion but is suggested if the bone age is normal and falls within 2 standard deviations of chronologic age. Normal prepubertal FSH and LH levels, normal or slightly elevated estradiol levels, normal pelvic sonographic findings, and normal growth are noted. Slightly elevated serum estradiol levels are seen more commonly in those who were very low-birthweight neonates (Klein, 1999; Nelson, 1983). Treatment consists of careful surveillance and reassurance that the remainder of pubertal development will progress at a normal age.

Adrenarche is the onset of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) production from the adrenal zona reticularis, which can be detected around age 6 years. The phenotypic result of adrenarche is axillary and pubic hair development, termed *pubarche*, which begins in girls at approximately age 8 years (Auchus, 2004). *Premature adrenarche* is defined therefore as the growth of pubic hair prior to age 8, but other signs of estrogenization or virilization are absent. Most girls will have an elevated DHEAS level, which suggests that the adrenal gland is maturating prematurely (Korth-Schultz, 1976). Some girls with premature adrenarche are found to later develop polycystic ovarian syndrome in adolescence (Ibanez, 1993; Miller, 1996). Others have a partial deficiency of 21-hydroxylase. Therefore, girls with premature adrenarche are screened for precocious puberty. When isolated, premature adrenarche treatment includes reassurance and monitoring at 3- to 6-month intervals for other signs of puberty.

Uterine bleeding that occurs once for several days or monthly, without other signs of puberty, is termed *premature menarche*. The condition is rare, and other sources of bleeding are considered and excluded first.

DELAYED PUBERTY

Puberty is considered delayed if no secondary sexual characteristics are noted by age 13, which is more than 2 standard deviations from the mean age. It is also considered delayed if menses have not commenced by age 15 or within 3 years of thelarche. Delayed puberty affects 3 percent of adolescents. Causes include those in Table 15-5. With the exception of constitutional delay, these other abnormalities are discussed in greater detail in Chapters 17, 18, and 19.

Constitutional delay is the most common cause, and adolescents lack both secondary sexual characteristics and pubertal growth spurt by age 13 years (Albanese, 1995; Malasanoa, 1997). The probable cause is a delay in reactivation of the GnRH pulse generator (Layman, 1994). Patients may be started on low-dose estrogen until puberty progresses, at which point estrogen may be discontinued. During low-dose estrogen treatment, it is not necessary to introduce progesterone withdrawal because in early puberty there is a similar long period of unopposed estrogen prior to ovulatory cycling.

SEXUALITY

Gender Identity

In most cases, phenotypic gender directs rearing practices, and girls are "raised as girls" and boys are "raised as boys." Gender-appropriate clothes and behaviors are adopted by the child and reinforced by parental approval. Practices in conflict with

gender are generally discouraged. However, young children will often explore various behaviors, both masculine and feminine, which make up normal experiences in the process of sex-role socialization (Mischel, 1970; Serbin, 1980).

In cases of ambiguous genitalia in the newborn, sexual assignment is more challenging. Initially, life-threatening disease such as congenital adrenal hyperplasia is excluded. As outlined in Chapter 19, gender assignment may be best delayed until test results identify genetic gender and the underlying problem. The final gender assignment in such cases is termed the sex of rearing and reflects the pattern of gender behavior to be emphasized. The final determination for the *sex of rearing* is based not only on the individual's karyotype but also on the functional capacity of their external genitalia. Early reconstructive surgery is performed less frequently. Instead, delays allow time for intersex children to reach an age of autonomous decision making, usually 18 years, regarding gender-defining surgery and hormone replacement.

Gender dysphoria describes individuals who perceive themselves to be different from their assigned gender. In the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), this is a recognized psychiatric diagnosis but is not considered a psychiatric disorder (American Psychiatric Association, 2013). That said, the discordance may cause depression and anxiety. At our institution, the Gender Education and Care Interdisciplinary Support (GENCIS) Clinic provides a multidisciplinary approach to treating the psychological, social, and medical needs of this population of children. Primary care of the transgender patient is described in Chapter 1 (p. 8).

Adolescent Sexuality

Adolescent sexuality develops during a period of rapid change that provides opportunities for adolescents to experience both risk-taking and health-promoting behaviors. Data from a large surveys of U.S. females show the percentage of those who become sexually active rises steadily after age 14, and 55 percent have had intercourse by age 18 (Abma, 2017; Liu, 2015).

Adolescents view providers as an important resource for information and education regarding healthy sexual development. However, many parents and educators oppose sexuality education because of concerns that providing such information will encourage the onset of intercourse, termed *coitarche*, and will raise intercourse frequency. On the contrary, studies find that such education actually lowers the frequency of sexual activity, increases contraceptive use, and reduces rates of unprotected intercourse, pregnancy, and STDs (Chin, 2012).

Oral sex is now more commonplace among adolescents. The National Survey of Family Growth in 2005 reported that one in four adolescents aged 15 to 19 years who had not had vaginal intercourse reported practicing oral sex with an opposite partner. Of those adolescents who practiced sexual intercourse, 83 percent of females and 88 percent of males stated they had engaged in oral sex (Mosher, 2005). Adolescents may see oral sex as an alternative way to maintain their "virginity," prevent pregnancy, or avoid STDs, or they may perceive it as a step on the way to engaging in sexual intercourse with a dating partner.

Sexual activity and partner violence appear to have a frequent association in adolescent populations (Chap. 1, p. 24). For example, Kaestle and Halpern (2005) noted that violent victimization was more likely to occur in romantic relationships that included sexual intercourse (37 percent) compared with those that did not (19 percent). Abma and colleagues (2010) reported that among females with coitarche before age 20, 7 percent described their first intercourse as nonvoluntary.

Contraception

Despite wide availability of contraceptive options, nearly one half of pregnancies in the United States are unintended (Finer, 2016). Of adolescents, almost 20 percent do not use contraception at first intercourse (Patel, 2016).

The most commonly used contraceptive by adolescents is the combination oral contraceptive (COC) pill. The intrauterine device (IUD) and the etonogestrel implant are long-acting reversible contraceptives (LARC), which are safe and suitable for adolescents (American College of Obstetricians and Gynecologists, 2017b, 2018a). One study of 179 adolescents found an 85-percent continuation rate after 1 year with the levonorgestrel-releasing IUD (Paterson, 2009). Ideally, this counseling begins prior to onset of sexual activity and includes discussion of emergency contraception. Many adolescents have misperceptions about contraception, including beliefs that it

may cause infertility or birth defects. Such concerns may be important topics during counseling.

Pelvic examination is not necessary when a contraceptive is prescribed if no other complaints are present. Moreover, guidelines from the American College of Obstetricians and Gynecologists (2018b) note that cervical cancer screening does not usually begin until age 21 regardless of sexual activity. HIV-positive status is an exception, and full screening recommendations are described in Chapter 29 (p. 630). Sexually active adolescents are counseled and screened for gonorrhea and chlamydial infection (U.S. Preventive Services Task Force, 2014). For adolescents, the preferred method is collection of a urine sample for nucleic acid amplification testing (NAAT). If positive, repeat testing follows 3 months after treatment. Other STDs are screened as clinically indicated.

HPV vaccination also can be offered, and the currently available vaccine in the United States is Gardasil 9. It is now approved by the Food and Drug Administration (2018) for females or males aged 9 through 45 years. Ideally at age 11 or 12 years, a series of two doses is provided. After the first dose, a second follows 6 to 12 months later. After age 15, three doses are needed (Robinson, 2017). In this instance, a second dose is administered 1 to 2 months later, and a third dose is given 6 months after the initial one. These vaccines are discussed further in Chapter 29 (p. 625).

To smooth the transition to adult care, the American College of Obstetricians and Gynecologists (2017c) has published guidelines, which include ages 18 to 26 years. Providers ideally discuss and screen for sexual and mental health, sleep disorders, nutrition, safety, and substance abuse.

Reproductive endocrinology is the study of hormones and neuroendocrine factors that are produced by and/or affect reproductive tissues. These tissues include the hypothalamus, anterior pituitary gland, ovary, endometrium, and placenta. A hormone is classically described as a cell product that is secreted into the peripheral circulation and that exerts its effects in distant target tissues (Fig. 16-1). This is termed *endocrine secretion*. Additional forms of cell-to-cell communication exist in reproductive physiology. *Paracrine* communication, common within the ovary, refers to chemical signaling between neighboring cells. *Autocrine* communication occurs when a cell releases substances that influence its own function. Production of a substance within a cell that affects that cell before secretion is termed an *intracrine* effect.

Neurotransmitters, in classic neural pathways, cross a small extracellular space called a synaptic junction and bind to dendrites of a second neuron (Fig. 16-2). Alternatively, these factors are secreted into the vascular system and are transported to other tissues where they exert their effects in a process termed *neuroendocrine secretion* or *neuroendocrine signaling*. One example is gonadotropin-releasing hormone (GnRH) secretion into the portal vasculature with effects on the gonadotropes within the anterior pituitary gland.

Normal reproductive function requires precise quantitative and temporal regulation of the hypothalamic-pituitary-ovarian axis (Fig. 16-3). Within the hypothalamus, specific centers or nuclei release GnRH in pulses. This decapeptide binds to surface receptors on the gonadotrope subpopulation of the anterior pituitary gland. In response, gonadotropes secrete glycoprotein gonadotropins—namely, luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—into the peripheral circulation. Within the ovary, LH and FSH bind to the theca and granulosa cells to stimulate folliculogenesis and ovarian production of steroid hormones (estrogens, progesterone, and androgens), gonadal peptides (activin, inhibin, and follistatin), and growth factors. Among other functions, these ovarian-derived

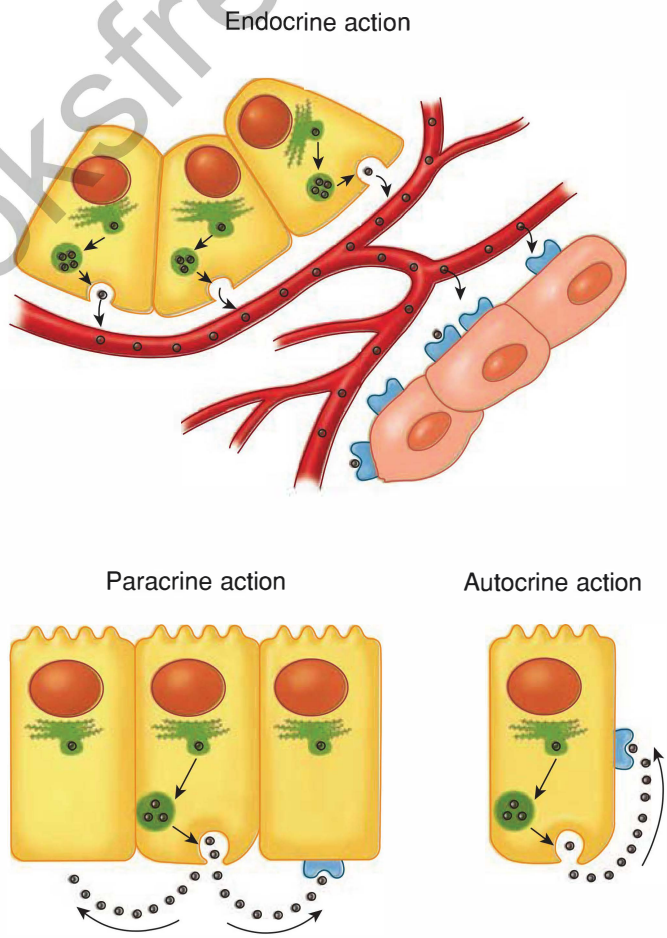

FIGURE 16-1 Different types of hormone communication. Endocrine: hormones travel through the circulation to reach their target cells. Paracrine: hormones diffuse through the extracellular space to reach their target cells, which are neighboring cells. Autocrine: hormones feed back on the cell of origin, without entering the circulation.

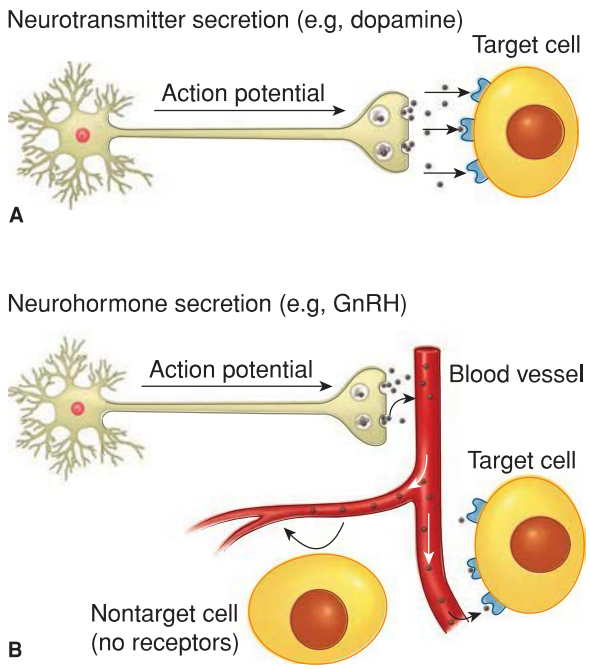

FIGURE 16-2 Types of neurotransmitter secretion. **A.** Classic neurotransmitter release and binding. Transmission of an action potential down a neural axon leads to release of neurotransmitters, which travel across a synaptic cleft to reach their target cell. **B.** Neurohormonal secretion. An action potential leads to release of neurotransmitters. In this instance, neurotransmitters enter into and travel through the circulation to reach their target organ.

factors feed back to the hypothalamus and pituitary gland to inhibit or, at the midcycle surge, to augment GnRH and gonadotropin secretion. The ovarian steroids are also critical for preparing the endometrium for placental implantation if pregnancy ensues.

HORMONE BIOSYNTHESIS AND MECHANISM OF ACTION

Hormones can be broadly classified as either steroids or peptides, each with their own mode of biosynthesis and mechanism of action. The receptors for these hormones can be divided into two groups. The first are receptors present on the cell surface, which in general bind water-soluble hormones, namely peptides. The second are primarily intracellular and bind lipophilic hormones such as steroids. Hormones are normally present in serum and tissues in very low concentrations. Therefore, receptors must have both high affinity and high specificity for their ligand to produce the correct biologic response.

Peptide Hormones: LH, FSH, and hCG

The gonadotropins LH and FSH are biosynthesized and secreted by the gonadotrope subpopulation of the anterior pituitary gland. These hormones play a critical role in stimulating ovarian steroidogenesis, follicular development, and ovulation. The closely related peptide human chorionic gonadotropin (hCG) is produced by placental trophoblast and is important for pregnancy maintenance.

LH, FSH, and hCG are heterodimers consisting of a common glycoprotein α-subunit linked to a unique β-subunit. This β-subunit provides functional specificity. Although glycoprotein α- and β-subunits can be found in their unassociated form in the circulation, these "free" subunits lack biologic activity. Nevertheless, their measurement may be useful in screening tests for conditions such as pituitary adenomas and pregnancy.

The LH and hCG β-subunits are encoded by two separate genes within a gene grouping called the LH/CG cluster. The amino acid sequence of the human LH and CG β-subunits demonstrates approximately 80-percent similarity. However, the hCG β-subunit contains an additional 24-amino-acid extension on the carboxy terminus. The presence of these

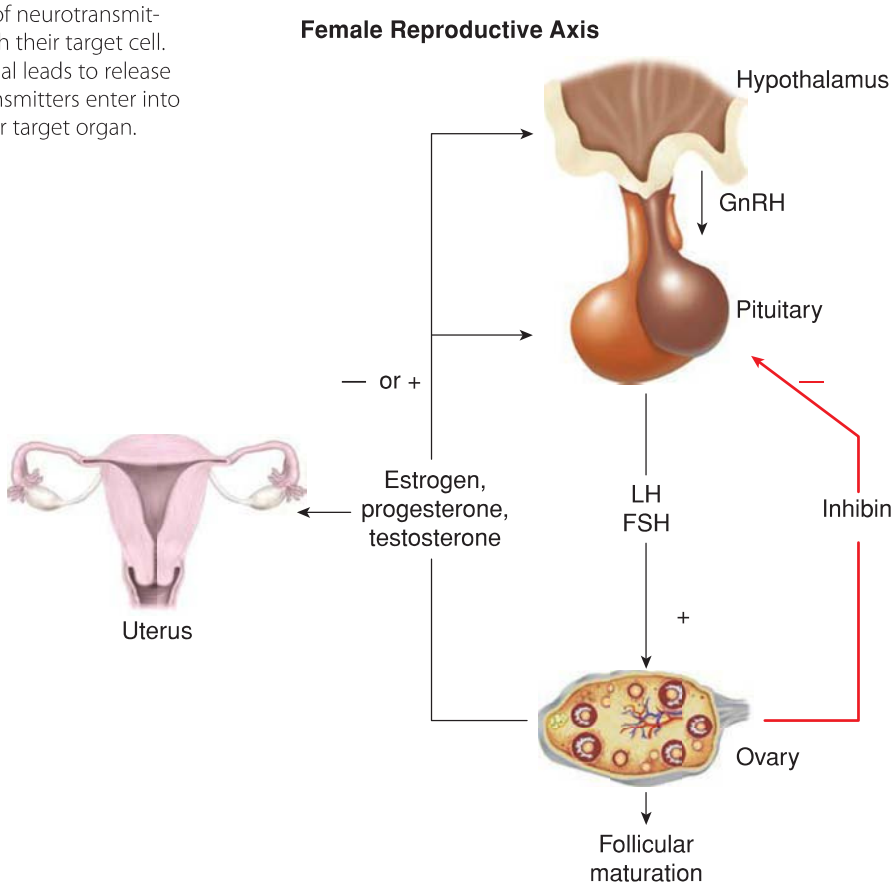

FIGURE 16-3 Positive and negative feedback loops seen with the hypothalamic-pituitary-ovarian axis. Pulsatile release of gonadotropin-releasing hormone (GnRH) leads to release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Effects of LH and FSH result in follicle maturation, ovulation, and production of the sex steroid hormones (estrogen, progesterone, and testosterone). Rising serum levels of these hormones exert negative feedback inhibition on GnRH and gonadotropin release. Sex steroid hormones vary in their effects on the endometrium and myometrium as discussed in the text. Inhibin, produced in the ovary, has a negative effect on gonadotropin release.

additional amino acids has allowed the development of highly specific assays that can distinguish LH from hCG.

In pituitary thyrotropes, the glycoprotein α-subunit interacts with the specific thyroid-stimulating hormone β-subunit to form thyroid-stimulating hormone (TSH). The similarity between TSH and hCG can have clinical implications. For example, molar pregnancies frequently produce very high levels of hCG, which can bind to TSH receptors, resulting in hyperthyroidism (Walkington, 2011).

Human Chorionic Gonadotropin

This glycosylated peptide hormone is produced by the placental syncytiotrophoblast. With hCG, the degree and type of glycosylated moieties attached to its peptide frame vary and may indicate pregnancy stage, placental function, or pathology (Fournier, 2015). One example is the hyperglycosylated hCG that is found more commonly in gestational trophoblastic neoplasia (GTN) (Chap. 37, p. 780).

hCG can be detected in serum as early as 7 to 9 days after the LH surge. In early pregnancy, hCG levels rise rapidly, doubling approximately every 2 days. Levels of this peptide hormone peak at approximately 100,000 mIU/mL during the first trimester of pregnancy. This is followed by a relatively sharp decline in early second-trimester concentrations and maintenance of lower levels throughout the remainder of pregnancy.

In early pregnancy, hCG binds to LH/CG receptors on corpus luteum cells and stimulates steroidogenesis in the ovary. To maintain endometrial integrity and uterine quiescence, hCG levels are critical for corpus luteum steroid production during early pregnancy before the placenta attains adequate steroidogenic capability. The transfer in production of estrogens and progesterone from the ovary to the placenta is often called the *luteal-placental shift*. In addition to effects on ovarian function, hCG exerts autocrine/paracrine effects in the placenta, promoting syncytiotrophoblast formation, trophoblast invasion, and angiogenesis.

As the placenta is the primary source for hCG production, measurement of plasma hCG levels has proved to be an effective screening tool for pregnancies with altered placental mass or function. Relatively elevated levels of hCG are observed in multifetal gestations and fetuses with Down syndrome. Markedly abnormal elevations in hCG levels are most often observed with GTN.

Lower hCG levels are observed in cases of poor placentation including ectopic pregnancy or spontaneous miscarriage. Recent efforts have focused on the development of algorithms using serial hCG levels and sonographic findings to accurately determine the status of a pregnancy of undetermined location (PUL) (Zee, 2014). Serial hCG measurements are helpful because the doubling time in normal pregnancy is relatively reliable.

hCG is also secreted by nontrophoblastic neoplasias and can serve as a useful tumor marker. Ectopic (nonplacental) production of hCG, either the intact dimer or the β-subunit, is frequently associated with germ cell tumors and has been reported in various tumors arising from the mucosal epithelium of the cervix, bladder, lung, gastrointestinal (GI) tract, and nasopharynx. It has been postulated that hCG inhibits apoptosis in these tumors and thereby allows rapid growth.

In addition to secretion by placental syncytiotrophoblast, hCG is produced by other cell types and presumably serves other functions (Cole, 2010). For example, cytotrophoblasts secrete a hyperglycosylated variant of hCG that may prove to be a sensitive marker of early pregnancy (Chuan, 2014). The pituitary gonadotropes also make small amounts of hCG. These concentrations rise in postmenopausal women and may be a rare cause of erroneously positive hCG testing in this age group (Cole, 2008).

Steroid Hormones

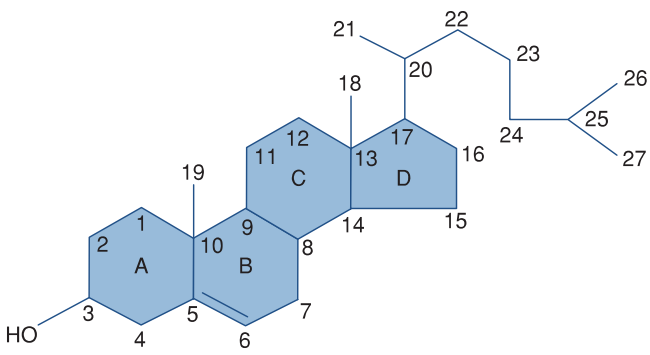
Classification

Sex steroids are divided into three groups based on the number of carbon atoms that they contain. Each carbon in this structure is assigned a number identifier, and each ring is assigned a letter (Fig. 16-4). The 21-carbon series includes progestogens, glucocorticoids, and mineralocorticoids. Androgens contain 19 carbons, whereas estrogens have 18.

Steroids are given scientific names according to a generally accepted convention in which functional groups below the plane of the molecule are preceded by the α symbol and those above the plane of the molecule are indicated by a β symbol. A Δ symbol indicates a double bond. Those steroids with a double bond between carbon atoms 5 and 6 are called Δ^5 *steroids* and include pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone. Those with a double bond between carbons 4 and 5 are termed Δ^4 *steroids* and include progesterone, 17-hydroxyprogesterone, androstenedione, testosterone, mineralocorticoids, and glucocorticoids.

Steroidogenesis

Sex steroid hormones are synthesized in the gonads, adrenal gland, and placenta. Cholesterol is the primary building block. All steroid-producing tissues, except the placenta, are capable of synthesizing cholesterol from the two-carbon precursor, acetate. Steroid hormone production, which involves at least 17 enzymes, primarily occurs in the mitochondria and the abundant smooth endoplasmic reticulum found in steroidogenic



Cholesterol

FIGURE 16-4 The chemical structure of cholesterol, which is the common precursor in sex-steroid biosynthesis. All sex steroids contain the basic cyclopentanophenanthrene molecule, which consists of three 6-carbon rings and one 5-carbon ring.

TABLE 16-1. Steroidogenic Enzymes

Enzyme	Cellular Location	Reactions

P450c11	Mitochondria	11-Hydroxylase 18-Hydroxylase 19-Methyloxidase
P450c17	ER	17-Hydroxylase 17,20-Lyase
P450c21	ER	21-Hydroxylase
P450arom	ER	Aromatase

ER = endoplasmic reticulum.

cells (Mason, 2002). These enzymes are members of the cytochrome P450 superfamily. As such, genes that encode these enzymes begin with *CYP*.

Steroidogenic enzymes catalyze four basic modifications of the steroid structure. These are: (1) side-chain cleavage (desmolase reaction), (2) conversion of hydroxyl groups to ketones (dehydrogenase reactions), (3) addition of a hydroxyl group (hydroxylation reaction), and (4) removal or addition of hydrogen to create or reduce a double bond (lyase reaction) (Table 16-1). The steroid biosynthesis pathway in simplified form is shown in Figure 16-5. This pathway is identical in all steroidogenic tissues. However, the distribution of products synthesized by each tissue is determined by the presence of requisite enzymes. For example, the ovary is deficient in 21-hydroxylase and 11β-hydroxylase and thus is unable to produce corticosteroids. Of note, many steroidogenic enzymes exist as multiple isoforms, each with different precursor preferences and directional activities. As a result, specific steroids may be produced via multiple pathways in addition to the classic pathway shown in Figure 16-5 (Auchus, 2009).

Of specific hormones, estrogens are synthesized by aromatization of C19 androgens by *aromatase*. This enzyme is a cytochrome P450 enzyme encoded by the gene *CYP19*. In addition to the ovary, aromatase is expressed in significant levels in adipose tissue, skin, and brain (Boon, 2010). Importantly, sufficient estrogen can be derived from peripheral aromatization to produce endometrial bleeding in postmenopausal women, especially those who are overweight or obese.

Circulating estrogens in the reproductive-aged female include estradiol (E_2), estrone (E_1), and estriol (E_3). Estradiol is the primary estrogen produced by the ovary during reproductive years. Levels are derived both from direct synthesis in the granulosa cells of developing follicles and through conversion of the less potent estrone. Estrone, the primary estrogen during menopause, is secreted mainly by the ovary. Estriol, the predominant estrogen during pregnancy, is secreted primarily from the placenta. However, both estrone and estriol can be derived from androstenedione in the periphery.

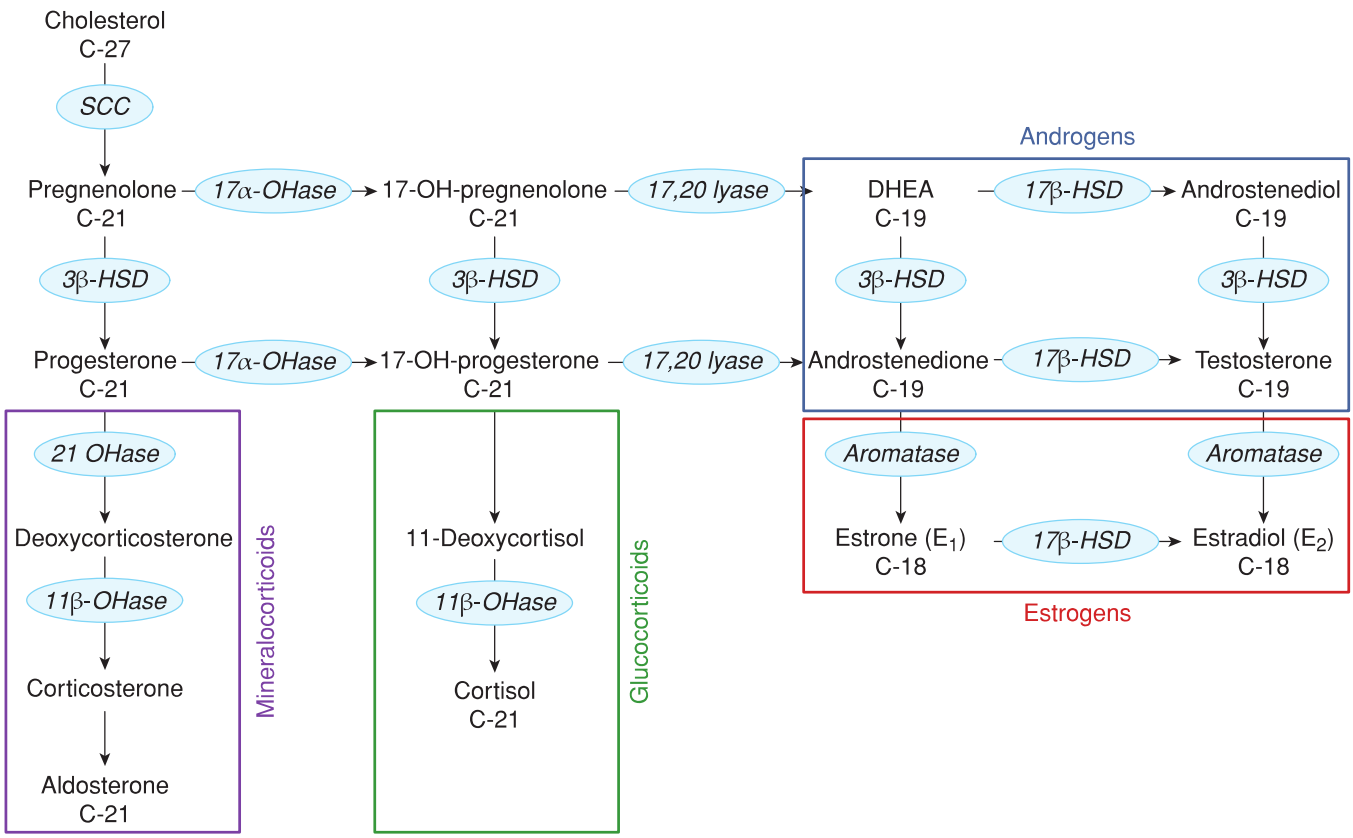

FIGURE 16-5 Steps in the steroidogenesis pathway. Enzymes are found within the blue ovals. The C18, C19, or C21 designation beneath the sex steroid reflects the number of carbon atoms it contains. Colored boxing groups these pathway products. 3β-HSD = 3β-hydroxysteroid dehydrogenase; 11β-OHase = 11β-hydroxylase; 17α-OHase = 17α-hydroxylase; 17β-HSD = 17β-hydroxysteroid dehydrogenase; 21OHase = 21-hydroxylase; DHEA = dehydroepiandrosterone; SCC = side-chain cleavage enzyme.

Within androgen synthesis, the 5α-reductase enzyme converts testosterone to dihydrotestosterone (DHT), a more potent androgen. DHT promotes transformation of vellus hair to terminal hair. Thus, medications that antagonize 5α-reductase are often effective in the treatment of hirsutism (Stout, 2010). This enzyme exists in two forms, each encoded by a separate gene. The type 1 enzyme is found in the skin, brain, liver, and kidneys. In contrast, the type 2 enzyme is expressed predominantly in male genitalia (Russell, 1994).

The ovary also produces androgens in response to LH stimulation of theca cell function. The two primary products are the relatively weak androgens androstenedione and dehydroepiandrosterone (DHEA). Smaller amounts of testosterone also are secreted. Although the adrenal cortex mainly produces mineralocorticoids and glucocorticoids, it also contributes to approximately one half of the daily production of androstenedione and DHEA and essentially all of the sulfated form of DHEA (DHEAS). In women, 25 percent of circulating testosterone is secreted by the ovary, 25 percent is secreted by the adrenal gland, and the remaining 50 percent is produced by peripheral conversion of androstenedione to testosterone (Table 16-2) (Silva, 1987).

The adult adrenal gland is composed of three zones. Each zone expresses a different complement of steroidogenic enzymes and as a result synthesizes different products. The zona glomerulosa lacks 17α-hydroxylase activity. Instead, it contains large amounts of aldosterone synthase (P450aldo) and therefore produces mineralocorticoids. The zona fasciculata and zona reticularis, both of which express the 17α-hydroxylase gene, synthesize glucocorticoids and androgens, respectively.

Steroid Hormone Transport in the Circulation

Most steroids in the peripheral circulation are bound to carrier proteins. These proteins may be specific, such as sex hormone-binding globulin (SHBG), thyroid-binding globulin, or corticosteroid-binding globulin, or nonspecific, such as albumin. Only 1 to 2 percent of circulating androgens and estrogens are unbound or free.

Only the unbound steroid fraction is believed to be biologically active. However, albumin's low affinity for sex steroids may allow steroids bound to this protein to exert some effects. The amount of free, biologically active hormone is inversely related to the amount of bound hormone, and the amount of bound hormone is a direct reflection of the levels of carrier protein. As a result, small changes in carrier protein expression can produce substantial alterations in steroid effect.

SHBG circulates as a homodimer that binds a single steroid molecule. This binding protein is synthesized primarily in the liver, although it has also been detected in the brain, placenta, endometrium, and testes. SHBG levels are increased by hyperthyroidism, pregnancy, and estrogen administration. In contrast, androgens, progestins, growth hormone (GH), insulin, and corticoids lower SHBG levels. Weight gain, particularly central body fat, can significantly blunt SHBG expression. In turn, this decreases bound hormone levels and raises active hormone levels (Hammond, 2012).

Free testosterone levels are the most commonly ordered free steroid hormone tests, but the most accurate assays are performed by only a few commercial laboratories (Rosner, 2007). Although mass spectrometry is considered the preferred measurement method, it has not been widely adopted due to complexity and cost (Kanakis, 2019). The more available *calculated* free levels are relatively inaccurate, and results should be interpreted with caution.

Fortunately, free testosterone level measurement is rarely necessary for clinical diagnosis in the female and is unlikely to add more information than the total testosterone level. For example, measurement of testosterone levels in patients with presumed polycystic ovarian syndrome (PCOS) is important to exclude an androgen-producing tumor, which will produce markedly elevated total testosterone levels. In contrast, normal or high-normal levels of total testosterone are consistent with the diagnosis of PCOS. Because testosterone lowers SHBG levels, patients with normal total testosterone levels, but with clinical evidence of hyperandrogenism (hirsutism and/or acne), invariably have either elevated free testosterone levels or increased sensitivity of the hair follicle and sebaceous glands.

Ultimately, steroids are metabolized mainly in the liver and to a lesser extent in the kidney and intestinal mucosa. Hydroxylation of estradiol results in production of estrone or catechol estrogens. These estrogens are then conjugated to glucuronides or sulfates to form water-soluble compounds for excretion in the urine. Accordingly, administration of certain pharmacologic steroid hormones may be contraindicated in those with active liver or renal disease.

TABLE 16-2. Contribution of the Ovaries and Adrenal Glands to Androgen Production

Product	Ovary	Adrenal Gland
Testosterone[a]	25%	25%
Androstenedione	50%	50%
DHEA	10%	90%
DHEAS	0%	>99%

[a]Remaining testosterone derived from conversion of androstenedione to testosterone in the periphery.
DHEA = dehydroepiandrosterone; DHEAS = DHEA sulfate.

RECEPTOR STRUCTURE AND FUNCTION

Steroid hormones and peptide factors differ in their specific receptor-mediated actions. Yet, both eventually lead to DNA transcription and protein production in the target cell.

G Protein–Coupled Receptors

These are cell membrane–associated receptors that bind peptide factors. These receptors consist of a hydrophilic extracellular domain, an intracellular domain, and a hydrophobic transmembrane domain that spans the cell membrane seven times. When bound to hormone, these receptors undergo a conformational change, activate intracellular signaling pathways, and, through a series of phosphorylation events, ultimately modulate transcription of multiple genes within the target cell (Fig. 16-6).

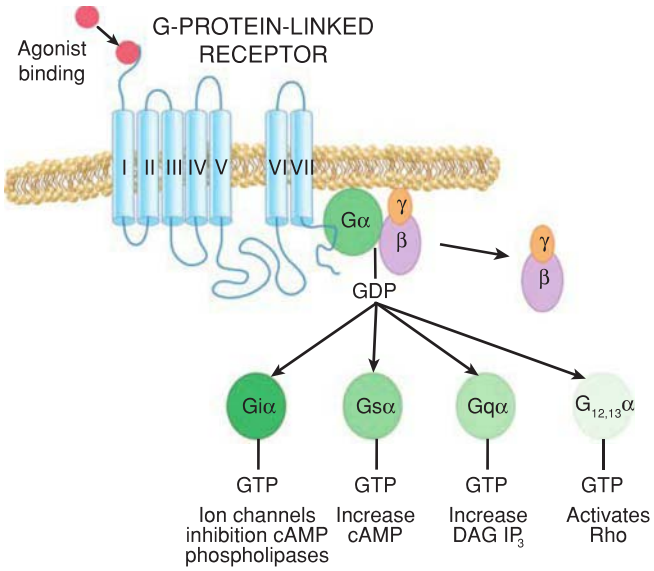

FIGURE 16-6 G protein–coupled receptors are integral transmembrane proteins that transduce extracellular signals to the cell interior. These receptors consist of seven membrane-spanning regions. Receptor occupation by an agonist promotes interaction between the receptor and the G protein on the membrane's inner surface. This induces an exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the G protein α subunit and dissociation of the α subunit from the βγ heterodimer. A large number of both activating and inhibiting α subunits exist, which allows for a wide array of responses. (From Mahendroo, 2018, with permission.)

The gonadotropin-releasing hormone receptor (GnRH-R) is a G protein–coupled receptor that has been identified in the ovary, testes, hypothalamus, prostate, breast, and placenta (Yu, 2011). Although data are still preliminary, GnRH and its receptor may form an autocrine/paracrine regulatory network in reproductive tissues including the ovaries and placenta in addition to the classic neuroendocrine hypothalamic-pituitary system (Kim, 2007; Lee, 2010).

Both LH and hCG bind to a single G protein–coupled receptor known as the LH/CG receptor. Relative to LH, hCG has a slightly higher affinity for the receptor and has a longer half-life. In contrast, FSH binds to a unique G protein–coupled receptor located on the granulosa cell membrane.

Within the ovary, the LH/CG receptor is expressed on theca cells, interstitial cells, and luteal cells. In the granulosa cells of preantral follicles, LH/CG receptor mRNA is nearly undetectable. However, in the differentiated granulosa cells found during follicular maturation, high levels of this receptor are observed. LH/CG and FSH receptors are also identified in endometrium, myometrium, and placenta (Stilley, 2014; Ziecik, 2007). The function of the receptor in these extraovarian tissues is poorly understood.

Steroid Hormone Receptors

Classification and Structure

Despite their structural similarities, estrogens, progestogens, androgens, glucocorticoids, and mineralocorticoids all interact with unique receptors known as *nuclear hormone receptors*. The nuclear receptor superfamily consists of three receptor groups. It contains: (1) those that bind steroidal ligands, (2) those that have affinity for nonsteroidal ligands such as thyroid hormone, and (3) orphan receptors. By definition, orphan nuclear receptors do not have an identified ligand. These are believed to be constitutively active, that is, they exhibit basal or intrinsic activity.

Free steroids diffuse into cells and combine with specific receptors (Fig. 16-7A) (Gruber, 2002). Members of this receptor superfamily exhibit a modular structure of distinct domains (Fig. 16-8) (O'Malley, 1999). Each region contributes distinct activities required for full receptor function. In general, nuclear receptors have two regions that are critical for gene activation, termed activation function 1 (AF1) and activation function 2 (AF2). AF1 is located in the A/B domain and is usually ligand independent. AF2 is in the ligand-binding domain (E) and is often hormone dependent. The highly conserved DNA-binding region (C) inserts into the DNA helix. Subsequently, steroid receptors enhance or repress gene transcription through interactions with specific DNA sequences, called *hormone response elements*, in the promoter region of target genes (Klinge, 2001).

Estrogen, Progesterone, and Androgen Receptors

Unliganded estrogen receptors (ERs) are located in the nucleus. In contrast, progesterone receptors (PRs), androgen receptor (AR), and those for mineralocorticoids and glucocorticoids are cytoplasmic in the absence of ligand. Ligand binding to these latter receptors allows translocation to the nucleus.

Two isoforms of estrogen receptors, ERα and ERβ, are encoded by separate genes (Kuiper, 1997). These receptors are differentially expressed in tissues and appear to serve distinct functions (Fig. 22-6, p. 484). For example, both ERα and ERβ are required for normal ovarian function. Mice lacking ERα are anovulatory and accumulate cystic follicles, whereas ovaries missing ERβ are normal histologically despite impaired ovulation (Couse, 2000).

The progesterone receptor also exists in multiple isoforms. Encoded from a single gene, PRA and PRB are identical except for an additional 164 amino acids at the amino terminus (Conneely, 2002). Similar to estrogen receptors, the PR isoforms are not interchangeable. For example, PRA is required for normal ovarian and uterine functions but is expendable in the breast (Lydon, 1996). In contrast to the estrogen and progesterone receptors, only one form of the androgen receptor has been identified.

Nongenomic Actions of Steroids

A subset of steroids, including estrogens and progestins, may alter cell function via nongenomic effects, that is, independent of the classic nuclear hormone receptors (see Fig. 16-7C). These nongenomic effects occur rapidly and may be mediated via cell-surface receptors, such as the G protein–coupled receptor 30 (GPR30) in the case of estrogen (Kowalik, 2013; Revelli, 1998). Pharmacologic agents under development specifically target these nongenomic effects to allow more precise therapy for steroid-sensitive reproductive disorders (Tang, 2019).

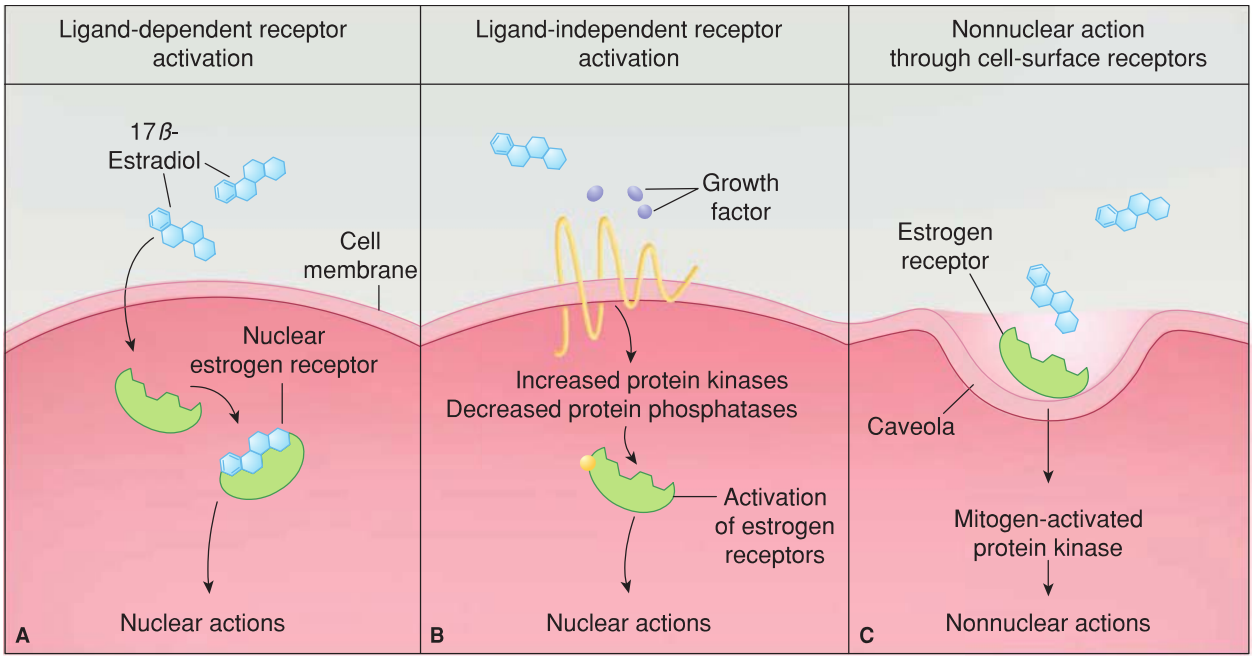

FIGURE 16-7 Estrogen receptor ligand–dependent and –independent activation. **A.** Classically, the estrogen receptor can be activated by estrogen. Unbound hormone is free to bind with empty steroid receptors found either in the cytoplasm or, more commonly, in the cell's nucleus. Hormone-bound receptors then bind to specific DNA promoter sequences. This binding typically leads to DNA transcription and eventually to specific protein synthesis. **B.** The estrogen receptor can also be activated independently of estrogen. Growth factors can increase the activity of protein kinases that phosphorylate different sites on the receptor molecule. This unbound, yet activated, receptor will then exert transcriptional effects. **C.** Nonnuclear estrogen-signaling pathways also can produce effects. Cell-membrane estrogen receptors are located in invaginations called caveolae. Estrogen binding to these estrogen receptors is linked to the mitogen-activated protein kinase pathway and results in a rapid, nonnuclear effect.

Receptor Expression and Desensitization

Many influences alter cellular response to sex steroids and peptide factors. The number of receptors within a cell or on the cell membrane is critical to attain maximum hormonal response.

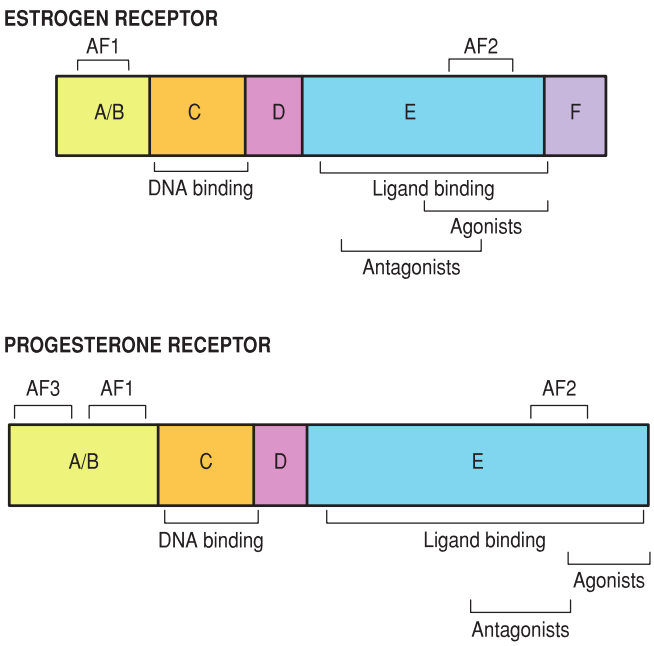

FIGURE 16-8 Functional domains within estrogen and progesterone receptors, including distinct sites for ligand and DNA binding.

Importantly, the number of receptors on a cell can be modified through gene transcription and receptor protein degradation.

Hormonally induced negative feedback of receptors is termed *homologous downregulation* or *desensitization*. Desensitization limits the duration of a hormonal response by decreasing the cell's sensitivity to a constant, prolonged level of hormone.

Within the reproductive system, desensitization is best understood for the GnRH receptor and is used clinically to produce a hypoestrogenic state. Pharmacologic agonists of GnRH, such as leuprolide acetate (Lupron), initially stimulate receptors on pituitary gonadotropes to cause a supraphysiologic release of both LH and FSH. Over a period of hours, agonists downregulate gonadotrope receptors, thus desensitizing them to further GnRH stimulation. Correspondingly, decreased gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration.

HORMONE IMMUNOASSAYS

Immunoassays

These tests use antibodies to detect most polypeptide, steroid, and thyroid hormones. They are sensitive and easily automated. Hormone concentration is usually reported as international units per volume rather than mass per volume (Table 16-3). When interpreting immunoassays, several concepts must be understood. These include reference standards, the "hook effect," biologic activity, normal ranges, and supplementary hormone levels.

TABLE 16-3. Reference Ranges for Selected Reproductive Steroids in Adult Human Serum

Steroid	Subjects	Reference Values
Androstenedione	Men	2.8–7.3 nmol/L
	Women	3.1–12.2 nmol/L
Testosterone	Men	6.9–34.7 nmol/L
	Women	0.7–2.8 nmol/L
Dihydrotestosterone	Men	1.0–3.10 nmol/L
	Women	0.07–.086 nmol/L
Dehydroepiandrosterone	Men/women	5.5–24.3 nmol/L
Dehydroepiandrosterone sulfonate	Men/women	2.5–10.4 μmol/L
Progesterone	Men	<0.3–1.3 nmol/L
	Women	
	Follicular	0.3–3.0 nmol/L
	Luteal	19.0–45.0 nmol/L
Estradiol	Men	<37–210 pmol/L
	Women	
	Follicular	<37–360 pmol/L
	Luteal	625–2830 pmol/L
	Midcycle	699–1250 pmol/L
	Postmenopausal	<37–140 pmol/L
Estrone	Men	37–250 pmol/L
	Women	
	Follicular	110–400 pmol/L
	Luteal	310–660 pmol/L
	Postmenopausal	22–230 pmol/L
Estrone sulfonate	Men	600–2500 pmol/L
	Women	
	Follicular	700–3600 pmol/L
	Luteal	1100–7300 pmol/L
	Postmenopausal	130–1200 pmol/L

First, to minimize assay-to-assay variability, a reference material is needed to standardize assays. Reference standards serve as anchors that can provide comparability across time and methods. Such reference preparations are produced by the World Health Organization (WHO) and the National Institutes of Health (NIH). More than 20 assay standards are available to measure LH, FSH, prolactin (PRL), and hCG. Thus, knowing which reference standard is used by a specific assay is essential, as results may differ significantly. Clinically, this can become an issue in patients with possible ectopic pregnancies when serial β-hCG levels are obtained at different health-care facilities.

Second, the hook effect can alter immunoassay result interpretation. With this, significantly elevated endogenous hormone levels saturate the assay's targeting antibody and thereby prevent required binding of the hormone to the assay. This creates a falsely low reading. One example is a negative urine pregnancy test result in a woman with a complete hydatidiform mole. When clinically suspected, specimen dilution can help resolve the hook effect.

Importantly, the amount of hormone present in a sample does not necessarily correlate with the biologic activity of that hormone. For example, PRL exists in multiple isoforms, many of which are immunologically detectable but not biologically active. Similarly, varying glycosylation patterns of gonadotropins at different times during the reproductive life span are believed to alter their biologic activity.

Another caveat is a result that lies in the "normal range." For many hormones, a stated normal range is often broad. As such, the hormone level of an individual may double, but remain within the normal range, although the result is actually abnormal for that individual.

Last, the addition of other hormone levels may be necessary to define the significance of a result. In the context of the pituitary gland and its target endocrine glands, it may be adequate to measure the pituitary hormone concentration alone. For example, high levels of circulating gonadotropins are almost invariably due to ovarian failure and loss of negative feedback. This is because pituitary overproduction of functional dimer is

rare. Conversely, low gonadotropin levels can be attributed to hypothalamic-pituitary dysfunction rather than ovarian failure. Thus, the measurement of ovarian-derived products such as estrogen can clarify the condition.

At times, the measurement of both pituitary and target hormone levels may be indicated. For example, in many laboratories, an abnormal TSH value will lead to "reflex," that is, automatic testing for thyroid hormone levels. Low levels of both a stimulating-hormone and target hormone indicate an abnormality in either hypothalamic or pituitary function. High levels of a target-gland hormone coupled with low levels of its stimulating pituitary hormone suggest autonomous secretion by the target organ such as occurs in the hyperthyroidism of Graves disease.

Stimulation and Suppression Tests

Stimulation tests may be useful when hypofunction of an endocrine organ is suspected. These tests use an endogenous stimulating hormone to assess the reserve capacity of the tissue of interest. The trophic hormone used may be a hypothalamic releasing factor such as GnRH or thyrotropin-releasing hormone (TRH). Alternatively, a substitute hormone may be used, such as hCG as a substitute for LH or leuprolide acetate for GnRH. The ability of the target gland to respond is measured by an increase in the appropriate hormone's plasma level. One example, the leuprolide stimulation test, may be used to evaluate abnormal pubertal development and is described in Chapter 15 (p. 330). Leuprolide substitutes for GnRH, as clinical-grade GnRH is often unavailable (Rosenfield, 2013).

Suppression tests may be performed when endocrine hyperfunction is suspected. For example, a dexamethasone suppression test may be given to a patient with suspected hypercortisolism (Cushing disease or syndrome). Described in full in Chapter 18 (p. 399), this test gauges the ability of dexamethasone to inhibit adrenocorticotropic hormone (ACTH) secretion and thus cortisol production by the adrenal. The failure of glucocorticoid treatment to suppress cortisol production would be consistent with primary hyperadrenalism.

HYPOTHALAMIC-PITUITARY AXIS

Anatomy

The hypothalamus consists of nuclei located at the base of the brain, just superior to the optic chiasm. Neurons within the hypothalamus form synaptic connections with other neurons throughout the central nervous system (CNS). A subset of the hypothalamic neurons within the arcuate, ventromedial, and paraventricular nuclei project to the median eminence. In the median eminence, a dense network of capillaries arises from the superior hypophyseal arteries (Fig. 16-9). These capillaries drain into portal vessels that traverse the pituitary stalk and then form a capillary network within the anterior pituitary gland (adenohypophysis). The primary direction of this hypophyseal portal system is from hypothalamus to pituitary. However, retrograde flow also exists. This creates an ultrashort feedback loop between the pituitary gland and hypothalamic neurons.

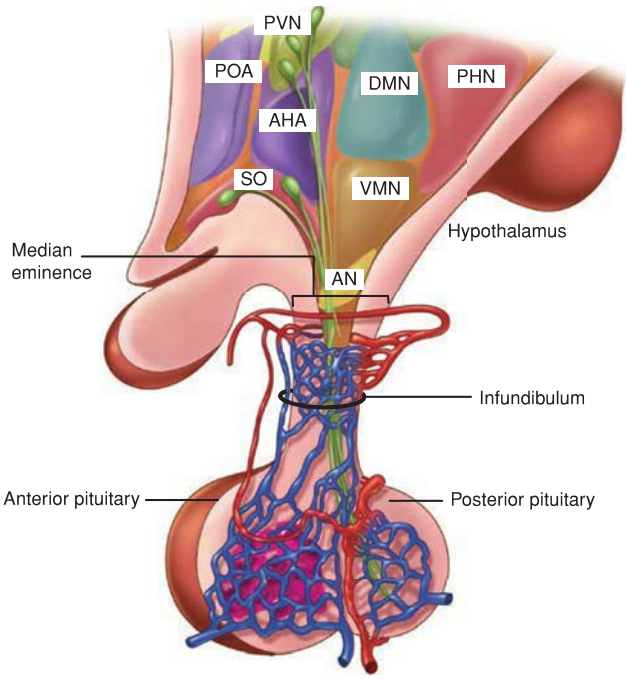

FIGURE 16-9 Sagittal section through the hypothalamus and pituitary gland with rostral structures to the left and caudal ones to the right. The hypothalamus is anatomically and functionally linked with the anterior pituitary by the portal system of blood supply. The posterior pituitary contains the axon terminals of neurons arising in the supraoptic (SO) nucleus and paraventricular nucleus (PVN) of the hypothalamus. AHA = anterior hypothalamic area; AN = arcuate nucleus; DMN = dorsomedial nucleus; PHN = posterior hypothalamic nucleus; POA = preoptic area; VMN = ventromedial nucleus. (Reproduced with permission from Mahendroo MS: Parturition. In Cunningham FG, Leveno KJ, Bloom SL, et al (eds): Williams Obstetrics, 23rd ed. New York, McGraw-Hill, 2010.)

The hypothalamus is thus a critical locus for integration of information from the environment, nervous system, and multiple organ systems.

The anterior pituitary gland consists of endocrine cells and is derived from an invagination of the Rathke pouch in the roof of the embryonic oral cavity. In contrast, the posterior pituitary gland (neurohypophysis) is neural tissue and consists of the axon terminals of magnocellular neurons arising in the supraoptic and paraventricular nuclei of the hypothalamus.

Hypothalamic Neuroendocrinology

The list of known neurotransmitters continues to expand as our understanding of their anatomic distribution, mode of regulation, and mechanism of action increases. Neurotransmitters can be classified as: (1) biogenic amines (dopamine, epinephrine, norepinephrine, serotonin, histamine), (2) neuropeptides, (3) acetylcholine, (4) excitatory amino neurotransmitters (glutamate, glycine, aspartic acid), (5) the inhibitory amino acid gamma-aminobutyric acid (GABA), (6) gaseous transmitters (nitric oxide, carbon monoxide), and (7) miscellaneous factors (cytokines, growth factors).

Clinically important neuropeptides within the reproductive axis include the endogenous opiates, kisspeptin, galanin,

neurokinin B, neuropeptide Y, galanin, and pituitary adenylate cyclase-activating peptide. This list is expanding rapidly with ongoing study and should not be considered exhaustive.

Endogenous Opiates

Central opioidergic neurons are important mediators of hypothalamic-pituitary function. Depending on the precursor peptide from which they are derived, these neuropeptides can be categorized into three classes: endorphins, enkephalins, and dynorphins. Of these, endorphins (endogenous morphines) are cleavage products of the proopiomelanocortin *POMC* gene, which also yields ACTH and α-melanocyte stimulating hormone (α-MSH) (Taylor, 1997). The endorphins serve a wide range of physiologic functions that include regulation of temperature, cardiovascular and respiratory systems, pain perception, mood, and reproduction. Several opioid receptor subtypes exist. Within the reproductive axis, activation of the μ-opioid receptor by β-endorphins is of critical importance (Seeber, 2019).

Proopiomelanocortin is produced in highest concentration in the anterior pituitary gland but is also expressed in the brain, sympathetic nervous system, gonads, placenta, GI tract, and lungs. The primary peptide synthesized from this pathway depends on the tissue source. For example, the predominant products in the brain are the opioids, whereas pituitary biosynthesis results principally in ACTH production.

Hypothalamic opioids play a central role in menstrual cyclicity by tonically suppressing the hypothalamic release of GnRH (Funabashi, 1994). Estrogen promotes endorphin secretion, and this is increased further with the addition of progesterone (Cetel, 1985). Thus, endorphin levels rise during the follicular phase, peak during the luteal phase, and drop markedly during menses. This pattern suggests that opioid tone and progesterone both decrease GnRH pulse frequency in the luteal phase, thus stimulating FSH secretion. For reasons that are not fully understood, opioid suppression of GnRH is relieved at the time of ovulation (King, 1984). In addition, functional hypothalamic amenorrhea due to eating disorders, intensive exercise, and stress correlates positively with higher endogenous opiate concentrations (Chap. 17, p. 378).

Kisspeptin

Hypothalamic kisspeptin neurons are involved in sexual differentiation, puberty initiation, and adult reproductive function. These neurons are part of the KNDy neuronal system, named for the coexpression of kisspeptin with neurokinin B and the opioid, dynorphin. Kisspeptin neurons send processes to GnRH neurons, allowing direct control of GnRH secretion. Interestingly, one group of kisspeptin neurons may mediate negative steroid feedback, whereas another may be responsible for the positive feedback observed before ovulation (Millar, 2014; Skorupskaite, 2014; Trevisan, 2018).

Kisspeptin expression has more recently been identified in numerous nonneuronal reproductive tissues. Ovarian kisspeptin is thought to play a role in follicular development, oocyte maturation, ovulation, and steroidogenesis (Hu, 2018). Uterine kisspeptin is implicated in endometrial decidualization. Kisspeptin is also expressed in the placenta throughout pregnancy (Cao, 2019).

Neurons located throughout the hypothalamus project to kisspeptin neurons, to GnRH neurons, and to other CNS areas that have roles in reproductive function. Moreover, kisspeptin neuronal activity is affected by inputs from throughout the CNS and by hormonal feedback. As such, modulation of kisspeptin and the KNDy system as therapeutic targets in pubertal disorders, hypothalamic amenorrhea, ovulation induction, and hot flashes are current investigational areas (Yang, 2016). Studies are also pursuing the use of circulating kisspeptin levels as a potential biomarker of pregnancy complications (Hu, 2019).

Other Hypothalamic Neuropeptides

Neuropeptide Y and galanin secretion varies in response to changes in energy level, such as with anorexia and obesity. Both of these neuropeptides alter GnRH pulsatility and potentiate GnRH-induced gonadotrope secretion (Lawrence, 2011; Peters, 2009). Recent interest has focused on gonadotropin-inhibitory hormone (GnIH)/RFamide-related peptide 3 (RFRP-3). Expressed in both the hypothalamus and anterior pituitary gland, this peptide is linked to gonadotropin suppression in response to stress (Iwasa, 2018).

Also secreted by hypothalamic neurons, pituitary adenylate cyclase–activating peptide (PACAP) enters the portal system. It binds to receptors on anterior pituitary cells and stimulates hormone secretion including gonadotropin secretion, albeit more weakly than GnRH. Gonadotropes themselves also secrete PACAP, suggesting an autocrine/paracrine role for this hormone within the pituitary. PACAP modulates GnRH-receptor expression and, conversely, GnRH alters PACAP-receptor expression on the gonadotrope cell surface. Furthermore, pituitary PACAP gene expression is markedly increased by GnRH (Halvorson, 2014). Thus, these two important neuropeptides are functionally linked at the level of the anterior pituitary.

Nutritional Status and Reproduction

Puberty onset and menstrual cyclicity are altered by nutritional status. As one component of this status, adipose functions as endocrine tissue and an energy storage depot and links reproductive capacity and energy homeostasis. Adipose-derived cytokine factors, termed *adipokines*, are members of the cytokine family and include *leptin* and *adiponectin*. Decreased energy reserves, which may develop with food scarcity, eating disorders, or certain types of exercise, are associated with lower circulating leptin and higher adiponectin levels.

Data suggest that a reduction in serum leptin concentrations increases activity of neuropeptide Y neurons to stimulate appetite. Conversely, a higher serum leptin level raises activity of proopiomelanocortin and kisspeptin neural networks. This in turn reduces food intake and stimulates GnRH secretion to thereby alter reproductive function (Chehab, 2014; Guzman, 2019). In addition to CNS effects, leptin likely affects reproductive function via alterations in gonadotrope GnRH receptor expression in the pituitary (Odle, 2018).

Adiponectin alters hypothalamic kisspeptin expression. Adiponectin receptor expression is documented throughout the hypothalamic-pituitary-gonadal axis and in the uterus, placenta, and developing embryo (Dobrzyn, 2018). Other

metabolic signals, such as pancreatic insulin and gastric ghrelin, also likely contribute to central mediation of reproduction.

Anterior Pituitary Hormones

The anterior pituitary gland contains five hormone-producing cell types: (1) gonadotropes (which produce LH and FSH), (2) lactotropes (PRL), (3) somatotropes (GH), (4) thyrotropes (TSH), and (5) adrenocorticotropes (ACTH). Of these, gonadotropes constitute approximately 10 to 15 percent of all hormonally active cells in the anterior pituitary (Childs, 1983).

With the exception of PRL, which is under tonic inhibition, pituitary hormones are stimulated by hypothalamic neuroendocrine secretion. Both of the gonadotropins, LH and FSH, are regulated by a single releasing peptide, GnRH, which acts on the anterior pituitary's gonadotrope subpopulation. Most gonadotropes contain secretory granules that contain both LH and FSH. However, a significant number of cells are monohormonal, that is, secrete only LH or only FSH.

Of the other pituitary-releasing hormones, corticotropin-releasing hormone stimulates biosynthesis and secretion of ACTH by the pituitary adrenocorticotropes. Thyrotropin-releasing hormone prompts thyrotrope secretion of TSH, also known as *thyrotropin*. Various hypothalamic secretagogues regulate expression of somatotrope-derived GH. Last, PRL expression is primarily under inhibitory regulation by dopamine. As a consequence of these regulatory mechanisms, damage to the pituitary stalk results in hypopituitarism for LH, FSH, GH, ACTH, and TSH, but an associated increase in PRL secretion.

Hypothalamic-Releasing Peptides

These are small peptides with short half-lives of a few minutes due to their rapid degradation. Hypothalamic-releasing peptides are released in minute quantities and are highly diluted in the peripheral circulation. Therefore, biologically active concentrations of these factors are locally restricted to the anterior pituitary gland. Clinically, the extremely low concentrations of these hormones render them essentially undetectable in serum. Thus, levels of their corresponding pituitary factors are measured as surrogate markers.

Gonadotropin-Releasing Hormone

GnRH is a decapeptide that has a half-life <10 minutes (Fig. 16-10). Pulsatile GnRH input is required for activation and maintenance of GnRH receptors. This characteristic is exploited clinically by administering long-acting GnRH agonists to treat steroid-dependent conditions such as endometriosis, leiomyomas, precocious puberty, breast cancer, and prostate cancer. These agonists compete with endogenous pulsatile GnRH at the receptor and thereby depress gonadotropin secretion. This in turn lowers serum ovarian sex steroid levels.

Various GnRH agonists and antagonists have been created by introducing amino acid modifications within the native GnRH sequence (Padula, 2005). A change in the glycine at position 6 led to agonists with longer half-lives. In contrast, changes in positions 1, 2, and 3 prevent GnRH-receptor activation, and examples of these antagonists are cetrorelix and ganirelix. Many of these products require subcutaneous injection, although nasal agonists are available. More recently and described in Chapter 11 (p. 244), an orally active nonpeptide antagonist, elagolix, was approved in the United States for treatment of endometriosis-associated pain (Taylor, 2018).

Humans express two forms of GnRH termed GnRH I and GnRH II (Cheng, 2005). The GnRH II peptide has a different expression pattern than the classically described GnRH and differs in receptor activation (Neill, 2002). Further research is needed to determine the overlapping and divergent functions of these two forms.

Migration of the GnRH Neurons. Many hypothalamic neurons arise within the CNS, but GnRH-containing neurons have a unique embryologic origin. Progenitor GnRH neurons originate in the medial olfactory placode and migrate along the vomeronasal nerve into the hypothalamus (Fig. 17-5, p. 378). A series of soluble factors regulate GnRH neuronal migration at specific locations along their migratory route. These factors include secreted signaling molecules such as GABA, adhesion molecules, and growth factors (Wierman, 2011). Failure of normal migration may stem from various genetic defects in these signaling molecules and can lead to Kallmann syndrome, which is discussed in Chapter 17 (p. 378).

GnRH cell bodies are located primarily within the arcuate nucleus. From these neuronal cell bodies, GnRH is axonally transported along the

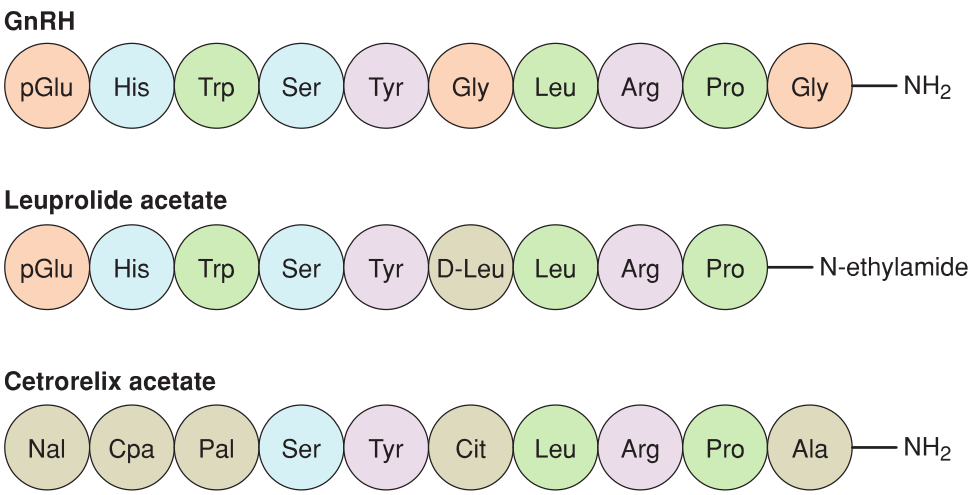

FIGURE 16-10 Amino acid composition of the decapeptide gonadotropin-releasing hormone (GnRH), the agonist leuprolide acetate, and the antagonist cetrorelix acetate. Glu = glutamic acid; His = histidine; Trp = tryptophan; Ser = serine; Tyr = tyrosine; Gly = glycine; Leu = leucine; Arg = arginine; Pro = proline; Nal = naphthylalanine; Cpa = cyanopropionic amino acid; Pal = pyridylalanine.

tuberoinfundibular tract to the median eminence. GnRH is then secreted into the portal system that drains directly to the anterior pituitary gland and stimulates gonadotropin biosynthesis and secretion. The number of GnRH neurons in the adult is strikingly low, with only a few thousand cells dispersed within the arcuate nucleus.

The olfactory origin of GnRH neurons and nasal epithelial cells suggest a link between reproduction and olfactory signals. Compounds released by one individual that affect other members of the same species are known as *pheromones*. Pheromones obtained from the axillary secretions of women in the late follicular phase accelerate the LH surge and shorten menstrual cycles of women exposed to these chemicals. Secretions from women in the luteal phase have the opposite effects. Thus, pheromones may be one mechanism by which women who are together frequently often exhibit synchronous menstrual cycles (Stern, 1998).

A subset of GnRH neurons sends projections into other areas of the CNS, including the limbic system. These projections are not required for gonadotropin secretion, but they may play a role in modulation of reproductive behavior (Nakai, 1978; Silverman, 1987).

Pulsatile GnRH Secretion. In elegant experiments, Knobil (1974) demonstrated that pulsatile delivery of GnRH to the pituitary gonadotropes is required to achieve sustained gonadotropin secretion. As shown in Figure 16-11, continuous infusion with GnRH rapidly diminishes both LH and FSH secretion. This effect is easily reversed with a return to pulsatile stimulation (Knobil, 1980).

Compared with the luteal phase, follicular-phase GnRH pulsatility is characterized by higher pulse frequency and lower amplitude. Higher pulse frequency preferentially stimulates LH, whereas lower frequency favors FSH secretion (Thompson, 2014). Therefore, changes in GnRH pulse frequency affect the absolute levels and the ratio of LH to FSH release.

Pulsatile activity was believed to be an intrinsic property of GnRH neurons. Although not yet definitive, more recent data suggest that kisspeptin neurons may actually drive GnRH pulsatility (Terasawa, 2019). Regardless, GnRH pulse rate and amplitude is modulated by a complex array of neurotransmitters and circulating hormones. In animal models, estrogen increases GnRH pulse frequency and therefore leads to an increase in LH levels relative to FSH levels. In contrast, progesterone decreases GnRH pulsatility. The increase in progesterone during the luteal phase may explain the preferential stimulation of FSH observed toward the end of this phase. This rise in FSH is critical for the initiation of follicular recruitment.

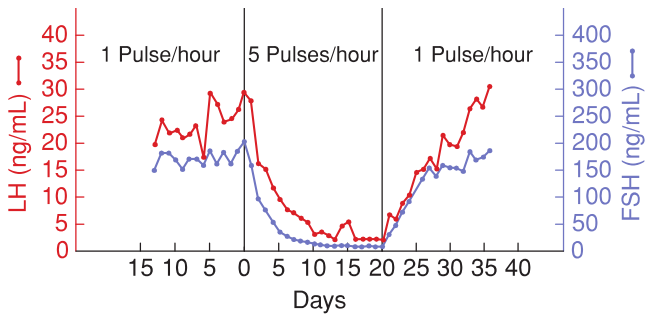

FIGURE 16-11 Changes in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels as gonadotropin-releasing hormone (GnRH) pulsatile release varies.

TABLE 16-4. Hypothalamic-Pituitary Products and Their End Organs

Hypothalamus	Pituitary	End Organ
GnRH	LH/FSH	Gonads
Dopamine	PRL	Breast
TRH	TSH	Thyroid
CRH	ACTH	Adrenal
GHRH	GH	Somatic

ACTH = adrenocorticotropin hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone–releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

Other Hypothalamic-Pituitary Axes

Dopamine and Prolactin

In contrast to the other anterior pituitary hormones, PRL release is primarily regulated via inhibition, specifically by dopamine (Table 16-4). These dopamine-containing fibers arise chiefly in the hypothalamic arcuate nucleus and project to the median eminence where dopamine enters the portal vessels. Prolactin-releasing factors, although less potent, include TRH, vasopressin, vasoactive intestinal peptide (VIP), endogenous opioids, and acetylcholine.

There are five forms of the dopamine receptor divided into two groups, D_1 and D_2. Cells in the anterior pituitary gland primarily express the D_2 subtypes. The medical treatment of prolactinomas has been improved in terms of both effectiveness and patient tolerance by the development of the D_2-specific ligands. For example, the dopamine agonist cabergoline is a D_2-specific ligand, whereas bromocriptine is nonspecific.

Thyrotropin-Releasing Hormone

As indicated by its name, thyrotropin-releasing hormone stimulates secretion of TSH from the anterior pituitary gland thyrotrope subpopulation. Of note, TRH also is a potent prolactin-releasing factor and results in a clinical link between hypothyroidism and secondary hyperprolactinemia (Messini, 2010).

TSH binds to specific receptors on the plasma cell membrane of thyroid gland cells. This stimulates thyroid hormone biosynthesis through an increase in thyroid gland size and vascularity. Thyroid hormone exerts negative feedback on TRH- and TSH-releasing cells.

Corticotropin-Releasing Hormone

This is the primary hypothalamic factor that stimulates synthesis and secretion of ACTH. Corticotropin-releasing hormone

(CRH) is distributed in multiple locations within the hypothalamus and other CNS areas. Release of CRH is stimulated by catecholaminergic input from other brain pathways and inhibited by endogenous opioids.

CRH binds to CRH receptors in the anterior pituitary gland to stimulate ACTH biosynthesis and secretion. In turn, ACTH stimulates glucocorticoid production by the adrenal gland's zona fasciculata and androgen production by its zona reticularis. CRH secretion is under negative-feedback regulation by circulating cortisol produced in the adrenal gland. In contrast, mineralocorticoid production by the zona glomerulosa is primarily regulated by the renin-angiotensin system. As a result, abnormalities in the CRH–ACTH pathway do not result in electrolyte disturbances.

Central CRH pathways are believed to mediate many stress responses (Kalantaridou, 2004). Clinically, in women with hypothalamic amenorrhea, CRH levels have been found to be elevated. Elevated levels of CRH inhibit hypothalamic GnRH secretion by direct action and by augmenting central opioid concentrations (Fig. 17-6, p. 379). This functional pathway may explain, in part, the association between hypercortisolism and menstrual abnormalities. However, recent work suggests that the link may be substantially more complex and involve multiple neural circuits and transmitters (McCosh, 2019).

Growth Hormone–Releasing Hormone

GH secretion by pituitary somatotropes is stimulated by hypothalamic growth hormone–releasing hormone (GHRH) and inhibited by somatostatin. GHRH is secreted primarily by the hypothalamus, but small quantities are released by placental and immune cells. In contrast, somatostatin is widely distributed in the CNS and in the placenta, pancreas, and GI tract.

As with GnRH, GHRH depends on pulsatile secretion to exert a physiologic effect. Exercise, stress, sleep, and hypoglycemia stimulate GH release, whereas free fatty acids and other factors related to adiposity blunt GH release. Estrogen, testosterone, and thyroid hormone also play a role in increased GH secretion.

GH stimulates skeletal and muscle growth, regulates lipolysis, and promotes the cellular uptake of amino acids. This hormone induces insulin resistance, and thus GH excess may be associated with new-onset diabetes mellitus. Most of the growth effects of GH are mediated via the insulin-like growth factors IGF-I and IGF-II. These growth factors are produced in high quantities in the liver. Many of the target tissues in which they exert local effects also synthesize IGFs. Within the ovary, IGF-I and IGF-II stimulate granulosa cell proliferation and steroidogenesis during folliculogenesis (Silva, 2009). IGFs also suppress GH secretion through negative-feedback mechanisms.

Posterior Pituitary Peptides

Neurons projecting to the posterior pituitary synthesize and secrete the nine-amino-acid cyclic peptides oxytocin and arginine vasopressin. Precursors for these peptides are produced in the neuronal cell body and transported down the axon in secretory granules. During transport, precursors are cleaved into mature peptides and a carrier protein—neurophysin (Verbalis, 1983). Activation of these neurons generates an axon potential that results in calcium influx and secretion of granule contents into the perivascular space. These secreted peptides then enter adjacent blood vessels for transport throughout the peripheral circulation.

Of these two peptides, oxytocin has significant roles in both parturition and lactation (Kiss, 2005). The role of oxytocin in labor initiation is disputed, as serum oxytocin levels are constant until the expulsive portion of labor (Blanks, 2003). Nevertheless, greater myometrial and decidual oxytocin-receptor expression has been noted near term, primarily due to a rise in estrogen levels.

Once labor is initiated, oxytocin is the primary mediator of myometrial contractility. Cervical and vaginal stimulation results in an acute release of oxytocin from the posterior pituitary in a process known as the *Ferguson reflex*. Clinically, oxytocin's ability to induce uterine contractions is exploited to induce or augment labor.

Vaginal distention, such as occurs with coitus, also augments oxytocin release. Based on this observation, oxytocin may be responsible for the rhythmic uterine and tubal contractions that aid sperm delivery to the oocyte. Oxytocin may also play a role in orgasm and ejaculation.

During lactation, PRL is critical for milk production in breast alveoli. The glandular cells of the alveoli are surrounded by a mesh of myoepithelial cells. Suckling triggers nerve impulses from mechanoreceptors in the nipple and areola that increase hypothalamic neuronal activity. Subsequent oxytocin release prompts the myoepithelial cells to contract and thereby express milk from the alveoli into the ducts and sinuses (Crowley, 1992). Other conditioned stimuli, such as the sight, sound, or smell of a baby or sexual arousal, can have similar effects.

Oxytocin expression has also been detected in the anterior pituitary, placenta, fallopian tubes, gonads, and corpus luteum (Williams, 1990). Its function in these tissues is unclear.

MENSTRUAL CYCLE

The "typical" menstrual cycle is 28 ± 7 days with menstrual flow lasting 4 ± 2 days and blood loss averaging 20 to 60 mL. By convention, the first day of vaginal bleeding is considered day 1 of the menstrual cycle. Menstrual cycle intervals vary among women and often for an individual woman at different times during her reproductive life. That said, cycles are least variable between the ages of 20 and 40 years. In a study of more than 2700 women, menstrual cycle intervals were most irregular in the 2 years following menarche and the 3 years preceding menopause (Treloar, 1967). Specifically, a trend toward shorter intervals followed by interval lengthening is common during the menopausal transition. In a recent study of more than 600,000 menstrual cycles, cycle length progressively shortened by 0.19 days per year for women aged 25 to 45 years (Bull, 2019).

When viewed from a perspective of ovarian function, the menstrual cycle can be defined as a preovulatory follicular phase and postovulatory luteal phase. Corresponding phases in the endometrium are termed the proliferative and secretory phases (Table 16-5). In the recent study just noted, a mean follicular-phase length of 16.9 days and mean luteal phase length

TABLE 16-5. Menstrual Cycle Characteristics

	Menstrual Cycle Phases		
Cycle day	1–5	6–14	15–28
Ovarian phase	Early follicular	Late follicular	Luteal
Endometrial phase	Menstrual	Proliferative	Secretory
Estrogen/progesterone	Low levels	Estrogen	Progesterone

of 12.4 days were found (Bull, 2019). As new data accumulate, reevaluation of the classic definition of cycle phase duration may be needed, but for now is not indicated (Fig. 16-12). For most women, the luteal phase of the menstrual cycle is stable. Thus, variations in normal cycle length generally result from variable duration of the follicular phase (Ferin, 1974).

The Ovary

Ovarian Morphology

The adult human ovary is oval with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. During the reproductive years, the ovary weighs between 5 and 10 g. It

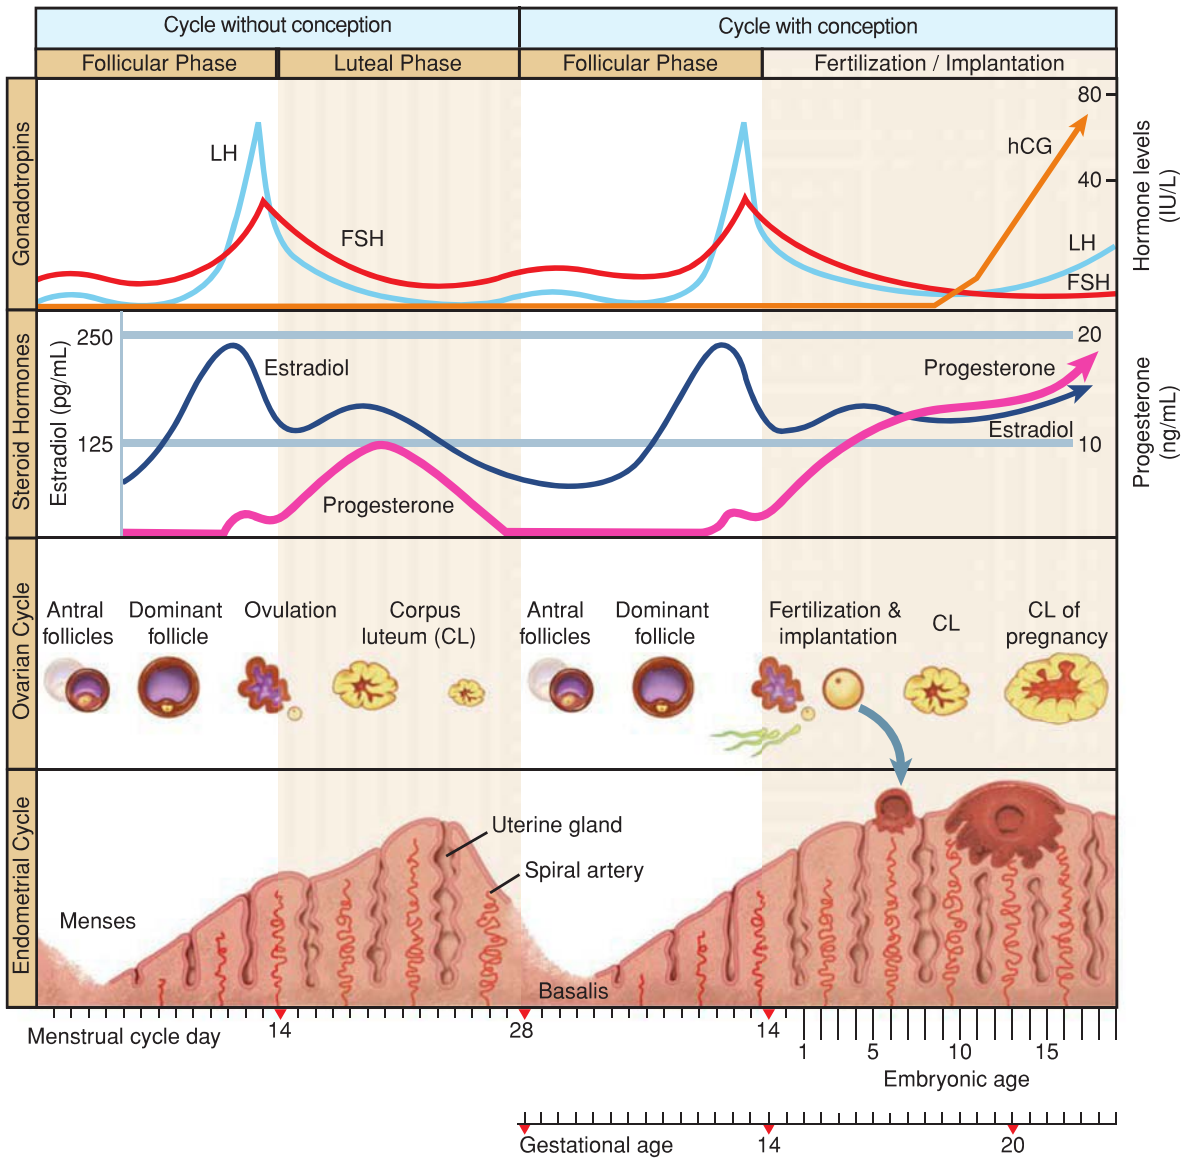

FIGURE 16-12 Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. If implantation occurs, the developing blastocyst will begin to produce human chorionic gonadotropin (hCG) and rescue the corpus luteum, thus maintaining progesterone production. FSH = follicle-stimulating hormone; LH = luteinizing hormone. (Reproduced with permission from Mahendroo MS, Cunningham FG: Implantation and placental development. In Cunningham FG, Leveno KJ, Bloom SL, et al (eds): Williams Obstetrics, 25th ed. New York, McGraw-Hill, 2018a.)

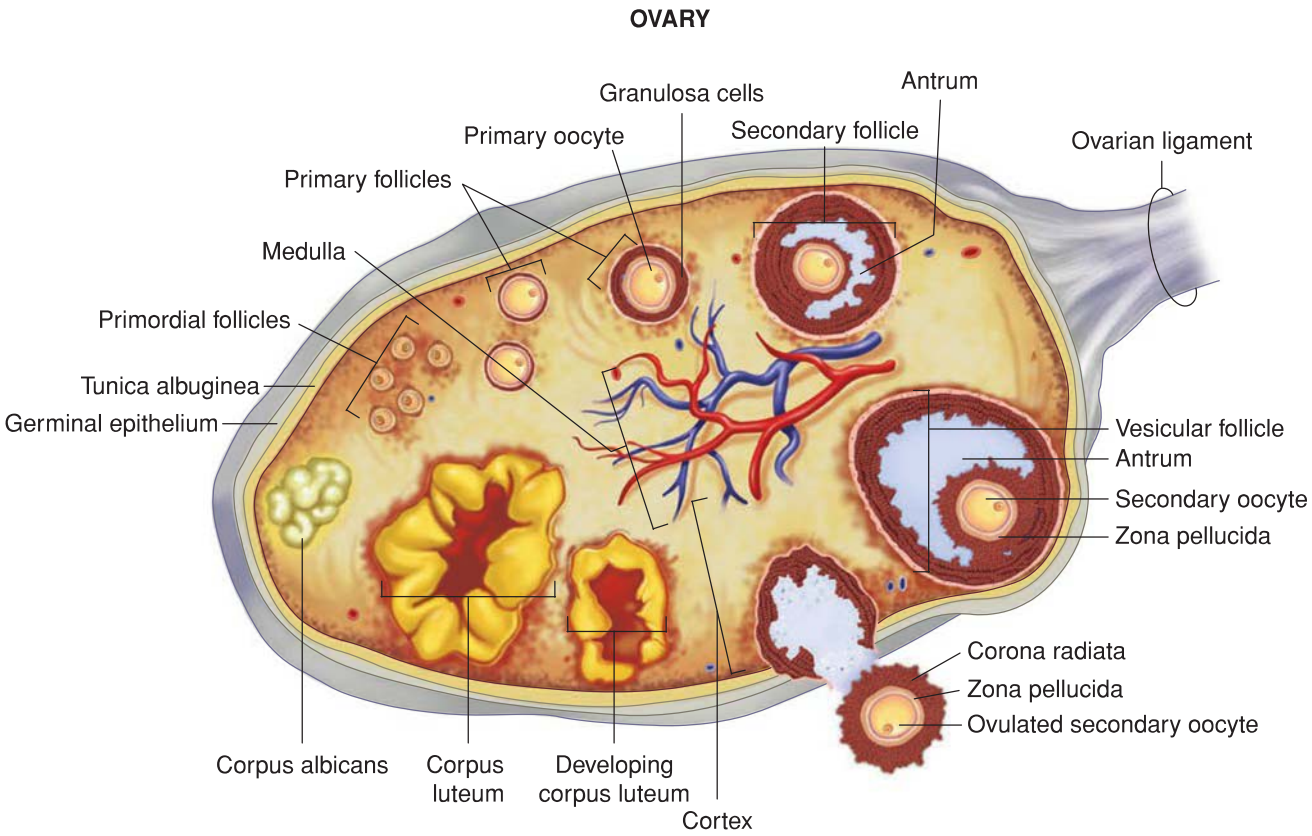

FIGURE 16-13 Ovarian anatomy and various sequential steps of follicular development.

is composed of three parts. The outer cortical region contains both the germinal epithelium and the follicles. The medullary region consists of connective tissue, myoid-like contractile cells, and interstitial cells. Last, the hilum contains blood vessels, lymphatics, and nerves that enter the ovary (Fig. 16-13).

Ovaries have two interrelated functions. The first is generation of mature oocytes. Second, production of steroid and peptide hormones creates an environment in which fertilization and subsequent blastocyst implantation in the endometrium can occur. Within each cycle, endocrine functions of the ovary correlate closely to the morphologic appearance and disappearance of follicles and the corpus luteum.

Ovarian Embryology

The ovary develops from three major cellular sources. First, primordial germ cells, which arise from the endoderm of the yolk sac, differentiate into the primary oogonia. Coelomic epithelial cells develop into granulosa cells, which surround the oocytes. Third, mesenchymal cells from the gonadal ridge become the ovarian stroma. Additional information regarding gonadal differentiation is found in Chapter 19 (p. 406).

Primordial germ cells can be seen in the yolk sac as early as the third week of gestation (Gosden, 2013). These cells begin their migration into the gonadal ridge during the sixth week of gestation and generate primary sex cords. The ovary and testes are indistinguishable by histologic criteria until approximately 10 to 11 weeks of fetal life.

After the primordial cells reach the gonad, they continue to multiply through successive mitotic divisions. Starting at 12 weeks' gestation, a subset of oogonia will enter meiosis to become primary oocytes. Primary oocytes are surrounded by a single layer of flattened granulosa cells, creating a primordial follicle.

Oocyte Loss with Aging

All oogonia either develop into primary oocytes or become atretic. Classic teaching states that additional oocytes cannot be generated postnatally. This differs markedly from the male, in whom sperm are produced continuously throughout adulthood. However, recent studies suggest that ovarian stem cells may be able to generate mature oocytes, providing hope for future female fertility preservation. Currently, these results remain preliminary and somewhat controversial (Martin, 2019; Notarianni, 2011; Virant-Klun, 2015).

The maximal number of oogonia is achieved at the 20th week of gestation, at which time 6 to 7 million oogonia are present in the ovary (Baker, 1963). Approximately 1 to 2 million oogonia are present at birth (Fig. 15-1, p. 321). Fewer than 400,000 are present at the initiation of puberty, of which fewer than 500 are destined to ovulate. Therefore, most germ cells are lost through atresia (Hsueh, 1996). Follicular atresia is thought not to be a passive, necrotic process, but rather a precisely controlled active process, namely apoptosis, which is under hormonal control. Apoptosis begins in utero and continues throughout reproductive life.

Oocyte Maturation

As previously mentioned, primary oogonia enter meiosis in utero to become primary oocytes. These oocytes are arrested

in development at prophase I during the first meiotic division. Meiotic progression resumes each month in a cohort of follicles. Meiosis I is completed in the oocyte destined for ovulation in response to the LH surge. Once again, the process is arrested, this time in the second meiotic metaphase. Meiosis II is completed only if the ovum is fertilized (Fig. 16-14).

Normal oocyte development requires cytoplasmic modifications in addition to meiotic maturation. Changes in

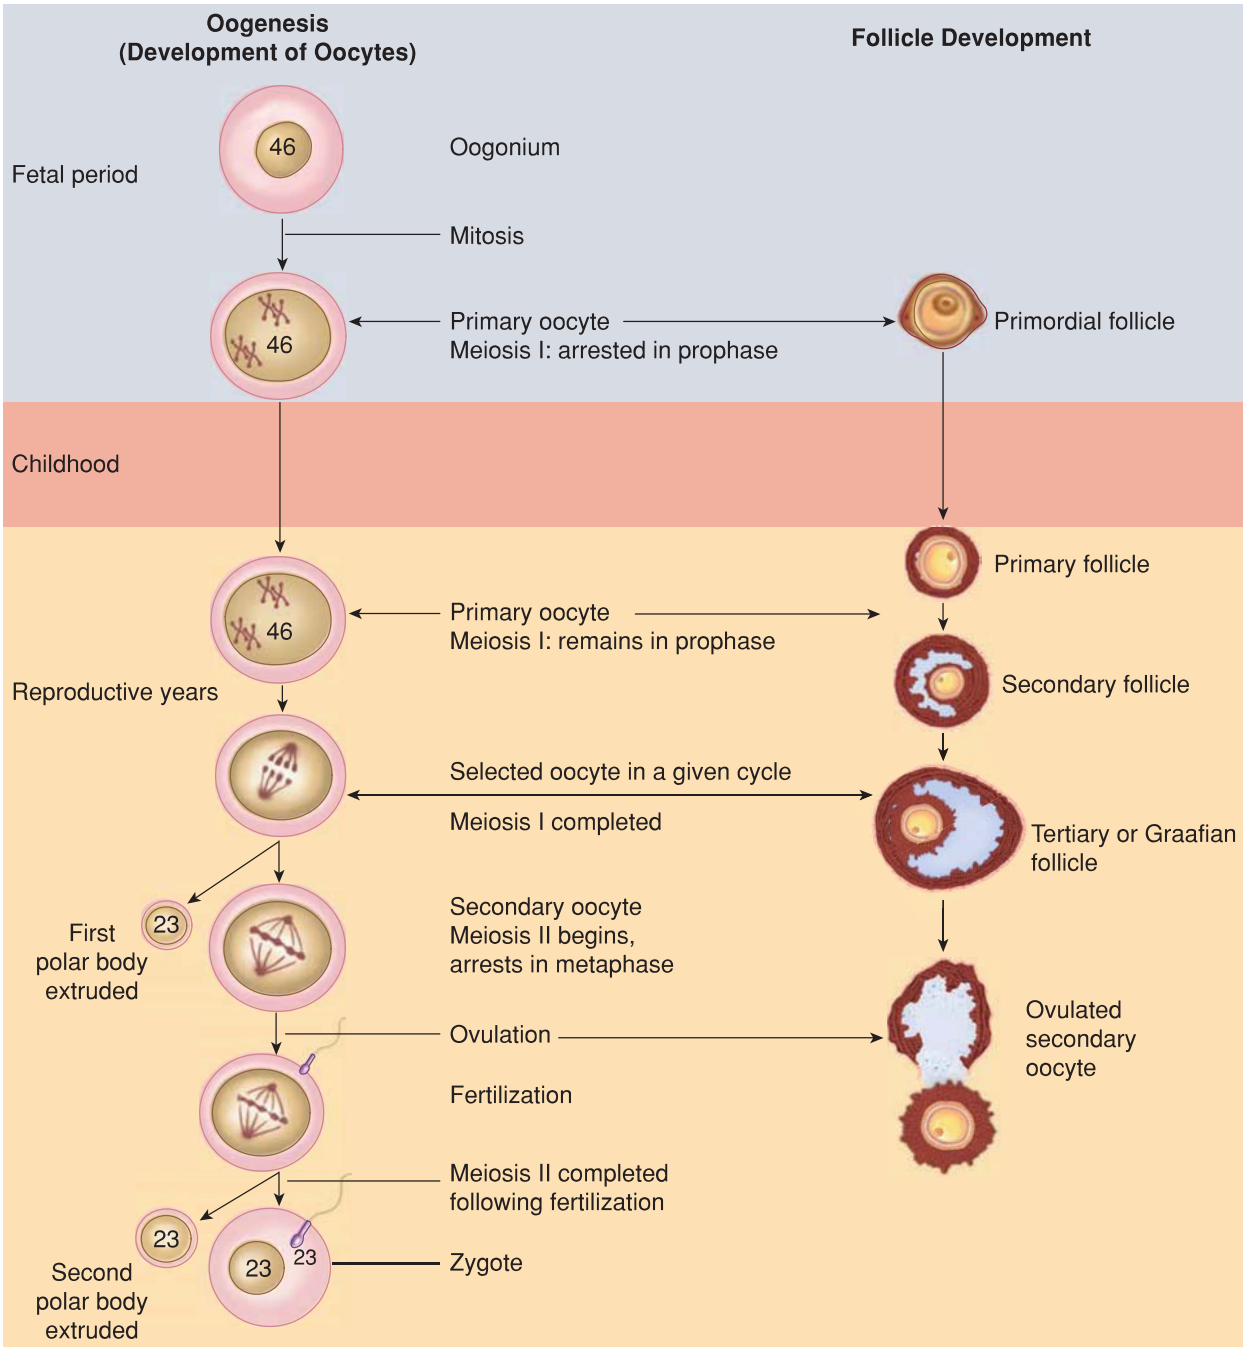

FIGURE 16-14 The steps of oocyte development and corresponding follicular maturation. In the fetal period, once the primordial germ cells arrive in the gonad, they differentiate into oogonia. Mitotic division of oogonia increases the population. Many oogonia further differentiate into primary oocytes, which begin meiosis. However, the process arrests after only prophase is completed. A primary oocyte with its surrounding epithelial cells is called a primordial follicle. In childhood, primary oocytes remain suspended in prophase I. Beginning in puberty and extending through the reproductive years, several primordial follicles mature each month into primary follicles. A few of these continue development to secondary follicles. One or two secondary follicles progress to a tertiary or graafian follicle stage. At this stage, the first meiotic division completes to produce a haploid secondary oocyte and a polar body. During this process, cytoplasm is conserved by the secondary oocyte. Consequently, the polar body is disproportionately small. The secondary oocyte halts meiosis at its second prophase. One of the secondary oocytes is then released at ovulation. If the oocyte is fertilized, completion of the second meiotic division follows. If fertilization fails to occur, then the oocyte degenerates before completion of the second meiotic division.

microtubules and actin filaments enable rearrangement of cellular organelles to allow successful polar body extrusion and fertilization (Coticchio, 2015). The critical cumulus cells that surround the oocyte modulate maturation both by cell-to-cell contact via gap junctions and by secretion of paracrine factors. Our growing understanding of these factors and processes is improving in vitro maturation protocols to aid fertility preservation and infertility treatments.

Stromal Cells

Ovarian stroma contains interstitial cells, contractile cells, and connective tissue cells. These last cells provide structural support to the ovary. The group of interstitial cells that surround a developing follicle and granulosa cells differentiates into theca cells. Under gonadotropin stimulation, theca cells grow in size and develop lipid stores, which is characteristic of steroid-producing cells (Saxena, 1972).

Another group of interstitial cells in the ovarian hilum are known as *hilus cells*. These closely resemble testicular Leydig cells, and hyperplasia or neoplastic changes in hilus cells may result in excess testosterone secretion and virilization. The normal role of these cells is unknown, but their intimate association with blood vessels and neurons suggest that they may convey systemic signals to the remainder of the ovary.

Ovarian Hormone Production

The normal functioning ovary synthesizes and secretes estrogens, androgens, and progesterone in a precisely controlled pattern determined, in part, by the pituitary gonadotropins, FSH and LH. The most important secretory products of ovarian steroid biosynthesis are progesterone and estradiol. However, the ovary also secretes quantities of estrone, androstenedione, testosterone, and 17α-hydroxyprogesterone. Sex steroid hormones play an important role in the menstrual cycle by preparing the uterus for implantation of a fertilized ovum. If implantation does not occur, ovarian steroidogenesis declines, the endometrium degenerates, and menstruation ensues.

Two-Cell Theory

Ovarian estrogen biosynthesis requires the combined action of LH and FSH on theca and granulosa cells. This concept is known as the two-cell theory of ovarian steroidogenesis (Fig. 16-15) (Peters, 1980). Until the late antral stage of follicular development, LH-receptor expression is limited to the theca compartment, and FSH-receptor expression is limited to granulosa cells.

Theca cells express all of the enzymes needed to produce androstenedione. This includes high levels of *CYP17* gene expression, whose enzyme product catalyzes 17-hydroxylation. This is the rate-limiting step in the conversion of progesterones to androgens (Sasano, 1989). This enzyme is absent in granulosa cells, and they are incapable of producing the androgenic precursors needed to produce estrogens. Granulosa cells therefore rely on theca cells. Namely, in response to LH stimulation, theca cells synthesize androstenedione and testosterone. These androgens are secreted into the extracellular fluid and diffuse across the basement membrane to the granulosa cells to provide precursors for estrogen production. In contrast to theca cells, granulosa cells have high levels of aromatase activity in response to FSH stimulation. Thus, granulosa cells efficiently convert androgens to estrogens and primarily to the potent estrogen estradiol. In sum, ovarian steroidogenesis is dependent on the effects of LH and FSH acting independently on the theca cells and granulosa cells, respectively.

Steroidogenesis across the Life Span

Circulating levels of the gonadotropins LH and FSH vary markedly at different ages of a woman's life. In utero, the fetal

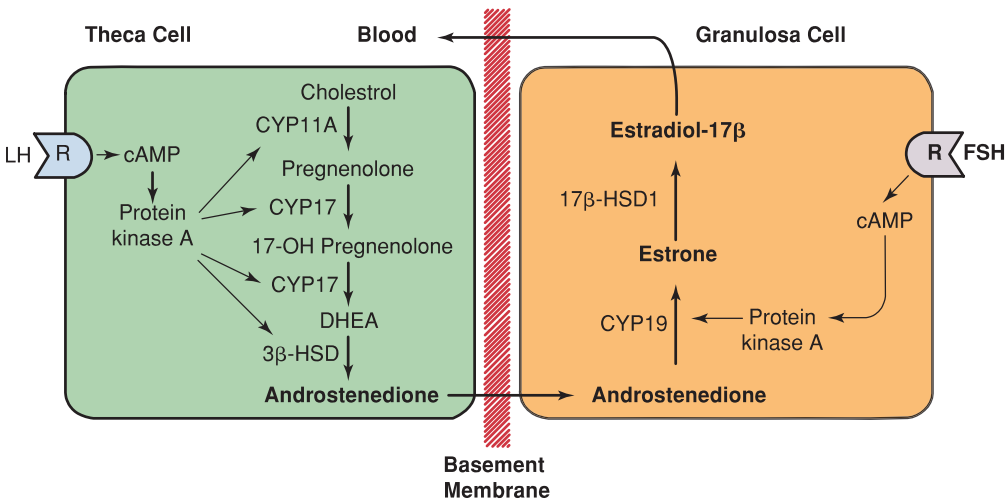

FIGURE 16-15 Diagram illustrates the two-cell theory of ovarian follicular steroidogenesis. Theca cells contain large numbers of luteinizing hormone (LH) receptors. Binding of LH to these receptors leads to cyclic AMP activation and synthesis of androstenedione from cholesterol. Androstenedione diffuses across the basement membrane of theca cells to enter granulosa cells of the ovary. Here, under the activation of follicle-stimulating hormone (FSH), androstenedione is converted by the enzyme aromatase to estrone and estradiol. cAMP = cyclic adenosine monophosphate; CYP11A = cholesterol side-chain cleavage enzyme; CYP17 = 17α-hydroxylase; CYP19 = aromatase; DHEA = dehydroepiandrosterone; 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17β-HSD1 = 17β-hydroxysteroid dehydrogenase; R = receptor.

human ovary can produce estrogens by 8 weeks' gestation. However, a minimal amount of steroid is actually synthesized during fetal development (Miller, 1988). During the second trimester, the plasma levels of gonadotropins rise to levels similar to those observed in menopause (Temeli, 1985). The fetal hypothalamic-pituitary axis continues to mature during this time, becoming more sensitive to the high circulating levels of estrogen and progesterone secreted by the placenta (Kaplan, 1976). Prior to birth and in response to these high steroid levels, fetal gonadotropins fall to low levels.

After delivery, gonadotropin levels in the neonate rise abruptly due to separation from the placenta and subsequent freedom from placental steroid feedback inhibition (Winter, 1976). The elevated gonadotropin levels persist for the first few months of life and then decline to low levels in early childhood (Schmidt, 2000). Multiple etiologies may explain the low gonadotropin levels during this time. The hypothalamic-pituitary axis has increased sensitivity to negative feedback, even by the low circulating levels of gonadal steroids at this stage. Moreover, a direct CNS role may maintain low gonadotropin levels. In support of this mechanism, low levels of LH and FSH are found even in children with gonadal dysgenesis who lack negative feedback by gonadal steroids.

With puberty onset, one early sign is a sleep-associated rise in LH secretion (Fig. 16-16) (Faiman, 1976). Over time, greater gonadotropin secretion is noted throughout the day. An increased FSH to LH ratio is typical in the premenarchal girl and postmenopausal woman. During the reproductive years, LH exceeds FSH levels and inverts this ratio. These increased gonadotropin levels stimulate ovarian estradiol production. The rise in estrogen levels prompts pubertal breast enlargement, which is termed *thelarche*, and internal and external genitalia maturation. This is accompanied by development of a female habitus, including a height growth spurt. Activation of the pituitary-adrenal axis results in greater adrenal androgen production and the associated pubertal development of axillary and pubic hair, termed *adrenarche* or *pubarche*. Increased gonadotropin levels ultimately lead to ovulation and subsequent menses. The first menstrual period defines *menarche*. This developmental process spans approximately 3 to 4 years and is discussed further in Chapter 15 (p. 321).

Following menopause, the postmenopausal ovary contains only a few follicles. As a result, plasma estrogen and inhibin levels decline markedly after cessation of ovulatory cycles. Through loss of this negative feedback, LH and FSH levels are strikingly elevated. High LH levels can stimulate production of C19 steroids (mainly androstenedione) in ovarian stromal cells. This ovarian-derived androstenedione and adrenal androgens can be converted by peripheral tissues to estrone, the principal serum estrogen in the postmenopausal women. The major site for the conversion of androstenedione to estrone is adipose tissue. Peripheral conversion of circulating androstenedione to estrone is directly correlated to body weight. For a given body weight, conversion is higher in postmenopausal women than in premenopausal women. However, these low circulating estrogen levels are usually not adequate to protect against bone loss.

Gonadal Peptides and the Menstrual Cycle

Of gonadal peptides, *inhibin*, *activin*, and *follistatin* modulate gonadotrope activity (de Kretser, 2002). As suggested by their names, inhibin decreases and activin stimulates gonadotrope function. Follistatin suppresses *FSHβ* gene expression, most likely by binding to and thereby preventing the interaction of activin with its receptor (Xia, 2009).

Inhibin and activin are closely related peptides. Inhibin consists of an α-subunit (unrelated to the LH and FSH glycoprotein α-subunit) linked by a disulfide bridge to one of two highly homologous β-subunits to form inhibin A ($\alpha\beta_A$) or inhibin B ($\alpha\beta_B$). Activin is composed of homodimers ($\beta_A\beta_A$, $\beta_B\beta_B$) or heterodimers ($\beta_A\beta_B$) of the same β-subunits as inhibin (Bilezikjian, 2012). In contrast, follistatin is structurally unrelated to either inhibin or activin.

Although originally isolated from follicular fluid, these peptides are expressed in the pituitary, ovary, testes, and placenta and in the brain, adrenal, liver, kidney, and bone marrow to provide diverse tissue-specific functions (Muttukrishna, 2004). Activin and follistatin most likely act as autocrine/paracrine factors in the tissues in which they are expressed, including the ovary.

In contrast, ovarian-derived inhibins circulate in significant concentrations and are believed to be critical for negative

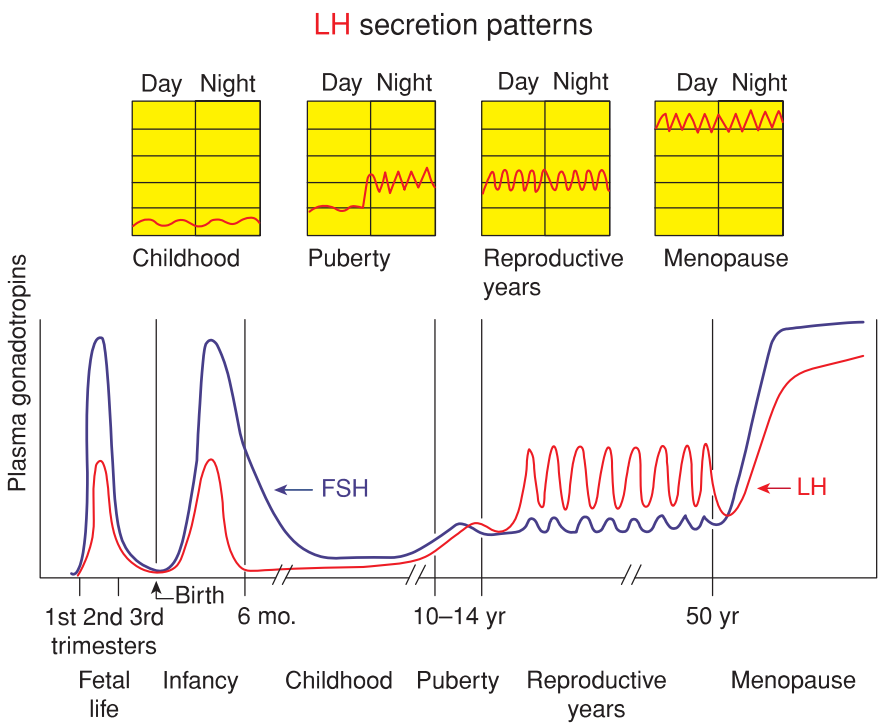

FIGURE 16-16 Variations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) during different life stages in the female.

feedback of gonadotropin gene expression. Specifically, during the early follicular phase, FSH stimulates the secretion of inhibin B by the granulosa cells (Fig. 16-17) (Buckler, 1989). However, increasing levels of circulating inhibin B blunt later FSH secretion in the follicular phase. During the luteal phase, regulation of inhibin production comes under the control of LH and switches from inhibin B to inhibin A (McLachlan, 1989). Inhibin B levels peak with the LH surge, whereas inhibin A levels peak a few days later, in the midluteal phase. All inhibin levels decline with the loss of luteal function and remain low during the luteal-follicular transition and early follicular phase. The inverse relationship between circulating inhibin levels and FSH secretion is consistent with a negative-feedback role for inhibin in regulating FSH secretion.

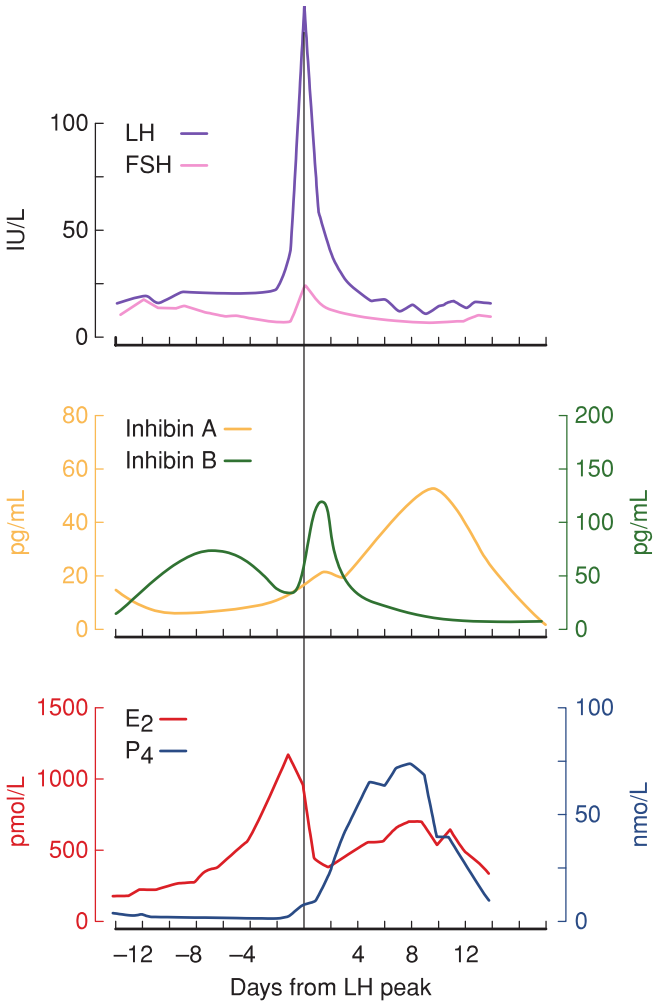

FIGURE 16-17 Gonadotropin, inhibin, and sex steroid level changes during a normal menstrual cycle. The top graph displays peaking of luteinizing hormone (LH) (purple line) and follicle-stimulating hormone (FSH) (pink line) levels. The middle graph shows changing levels of inhibin A and inhibin B. Note that inhibin B levels (green line) peak temporally near the midcycle surge in the LH level, whereas maximal elevation of inhibin A (orange line) occurs several days following this peak. In the bottom graph, elevations in estradiol levels (red line) are noted prior to the surge in LH levels and in the midluteal phase. Progesterone levels (blue line) peak in the midluteal phase. E_2 = estradiol; P_4 = progesterone.

Distinct from these three peptides, insulin-like growth factors also mediate ovarian function. Only IGF-II is involved in primordial follicle development, but both IGF-I and IGF-II stimulate growth of secondary follicles. Gonadotropins stimulate IGF-II production in theca cells, granulosa cells, and luteinized granulosa cells. Receptors for IGF are expressed on the theca and granulosa cells, supporting an autocrine/paracrine action in the follicle. FSH also mediates expression of IGF-binding proteins. This system, although complex, allows additional fine-tuning of intrafollicular activity (Silva, 2009).

Follicular Development

Follicle Stages

Development begins with primordial follicles that were generated during fetal life (see Fig. 16-14). These follicles consist of an oocyte arrested in the first meiotic division surrounded by a single layer of flattened granulosa cells. The follicles are separated from the stroma by a thin basement membrane. Preovulatory follicles are avascular. As such, they are critically dependent on diffusion and on the later development of gap junctions for obtaining nutrients and clearing metabolic waste. Diffusion also allows passage of steroid precursors from the theca cell layer to the granulosa cell layer.

In the primary-follicle stage, the granulosa cells of developing follicles become cuboidal, increase in number, and form a pseudostratified layer. Intercellular gap junctions develop between adjacent granulosa cells and between granulosa cells and the developing oocyte (Albertini, 1974). Gap junctions allow cells without gonadotropin receptors to receive signals from cells with receptor expression. As a result, hormone-mediated effects can be transmitted throughout the follicle.

During this stage, the oocyte secretes products to form an acellular coat known as the *zona pellucida*. The human zona pellucida contains at least three proteins, named *ZP1*, *ZP2*, and *ZP3*. In current physiologic models, receptors on the acrosome head of the sperm recognize ZP3. This interaction releases acrosomal contents that permit penetration of the zona pellucida and ovum fertilization. Enzymes released from the acrosome induce alterations in ZP2 resulting in hardening of the coat, which prevents fertilization of the oocyte by more than one sperm (Gupta, 2015).

Development of a secondary, or preantral, follicle includes final oocyte growth and a further increase in granulosa cell number. The stroma around the granulosa cell layer differentiates into the *theca interna* and the *theca externa* (Eppig, 1979).

Tertiary follicles, also called *antral follicles*, form from ongoing development in selected oocytes. In these, follicular fluid collects between the granulosa cells, ultimately producing a fluid-filled space known as the *antrum*. Granulosa cells in the antral follicle are histologically and functionally divided into two groups. The granulosa cells surrounding the oocyte form the *cumulus oophorus*, whereas the granulosa cells surrounding the antrum are known as *mural granulosa cells*. Antral fluid consists of a plasma filtrate and factors secreted by the granulosa cells. These locally produced factors, which include estrogen and growth factors, are present in substantially higher concentrations in follicular fluid than in the circulation and are likely

critical for successful follicular maturation (Asimakopoulos, 2006; Silva, 2009). Further accumulation of antral fluid results in rapid follicular size growth and development of a preovulatory follicle, also called a *graafian follicle* (Hennet, 2012).

During this process, early stages of development (up to the secondary follicle) do not require gonadotropin stimulation and thus are said to be "gonadotropin-independent." Final follicular maturation requires adequate amounts of circulating LH and FSH and is therefore said to be "gonadotropin-dependent" (Butt, 1970). Data suggest that progression from gonadotropin-independent to -dependent stages is not as discrete as previously believed.

Selection Window

Follicular development is a multistep process, which proceeds over at least 3 months and culminates in ovulation from a single follicle. Each month, a group of follicles known as a *cohort* begins a phase of semisynchronous growth. The cohort size appears to be proportional to the number of inactive primordial follicles within the ovaries and ranges from 3 to 11 follicles per ovary in young women (Hodgen, 1982; Pache, 1990). Importantly, the ovulatory follicle is recruited from a cohort that began development two to three cycles prior to the current ovulatory cycle. During this time, most follicles will die as they will not be at an appropriate stage of development during the selection window.

During the luteal-follicular transition, a small rise in FSH levels is responsible for selection of the single dominant follicle that will ultimately ovulate (Schipper, 1998). As previously described, theca cells produce androgens and granulosa cells generate estrogens. Estrogen levels rise with growing follicular size, enhance the effects of FSH on granulosa cells, and create a feed-forward action on follicles that produce estrogen.

Intrafollicular levels of the insulin-like growth factors are believed to synergize with FSH to help select the dominant follicle (Son, 2011). In addition, vascular endothelial growth factor (VEGF) levels around the follicle that will be selected are elevated. VEGF-associated enhancement of vascularity would presumably expose this follicle to higher levels of circulating factors, such as FSH.

Granulosa cells also produce inhibin B, which passes from the follicle into the plasma and specifically inhibits the release of FSH, but not of LH, by the anterior pituitary gland. The combined production of estradiol and inhibin B by the dominant follicle results in the decline of follicular-phase FSH levels and may be responsible at least in part for the failure of the other follicles to reach preovulatory status during any one cycle.

Estrogen-Dominant Microenvironment

Ongoing follicular maturation requires the successful conversion from an "androgen-dominant" microenvironment to an "estrogen-dominant" one. At low concentrations, androgens stimulate aromatization and contribute to estrogen production. However, intrafollicular androgen levels will rise if aromatization in the granulosa cells lags behind androgen production by the thecal layer. At higher concentrations, androgens are converted to the more potent 5α-androgens, such as dihydrotestosterone. These androgens inhibit aromatase activity, cannot be aromatized to estrogens, and inhibit FSH induction of LH-receptor expression on the granulosa cells (Gervásio, 2014).

This model predicts that follicles that lack adequate FSH receptor and granulosa cell number will remain primarily androgenic and will become atretic. An increased androgen-to-estrogen ratio is found in the follicular fluid of atretic follicles, and several studies demonstrate that high estrogen levels prevent apoptosis.

Insulin-like growth factor I also has apoptosis-suppressing activity and is produced by granulosa cells. This action of IGF-I is diminished by certain IGF-binding proteins that are present in the follicular fluid of atretic follicles. The action of FSH to prevent atresia may therefore result, in part, from its ability to stimulate IGF-I synthesis and suppress synthesis of IGF-binding proteins.

Menstrual Cycle Phases

Follicular Phase

During the end of a previous cycle, estrogen, progesterone, and inhibin levels decline abruptly, whereas circulating FSH levels rise (Hodgen, 1982). As just described, this higher FSH level is responsible for recruitment of the follicle cohort that contains the follicle destined for ovulation. Despite general belief, sonographic studies in women demonstrate that ovulation does not alternate sides but occurs randomly from either ovary (Baird, 1987).

In women with waning ovarian function, FSH levels in the early follicular phase are elevated relative to those of younger women, presumably due to a loss of ovarian inhibin production in the prior luteal phase. Thus, measurement of cycle-day-3 FSH and estradiol levels is frequently performed in infertility clinics. The accelerated rise in serum FSH levels results in more robust recruitment of follicles and may explain both the shortened follicular phase observed in older reproductive-aged women and their increased incidence of spontaneous twinning.

During the midfollicular phase, follicles produce greater amounts of estrogen and inhibin. This leads to a decline in FSH levels through negative feedback. This drop in FSH levels is believed to aid selection of the follicle destined to ovulate, termed the *dominant follicle*. Based on this theory, remaining follicles, which will undergo atresia, express fewer FSH receptors and are unable to respond adequately to declining FSH levels. As noted earlier, decreased VEGF expression also plays a role by decreasing surrounding vascularity and delivery of circulating factors to these follicles (Ravindranath, 1992).

During most of follicular development, granulosa cells respond to FSH by raising their cell number, augmenting aromatase expression, and, in the presence of estradiol, increasing expression of LH receptors on the granulosa cells. With LH-receptor expression during the late follicular phase, granulosa cells begin to produce small amounts of progesterone. This progesterone decreases granulosa cell proliferation and thereby slows follicular growth (Chaffkin, 1992).

Ovulation

Toward the end of the follicular phase, estradiol levels increase dramatically. Although not completely understood but perhaps

related to changes at the kisspeptin neurons, the rapid estradiol level rise triggers a switch from negative to positive feedback at both the hypothalamus and anterior pituitary gland. This feedback change generates a surge in LH levels. Estradiol concentrations of 200 pg/mL for 50 hours are necessary to initiate this LH surge (Young, 1976). A small preovulatory rise in progesterone concentrations generates an FSH level surge, which occurs in tandem with the LH surge (McNatty, 1979). Progesterone may also augment the ability of estradiol to trigger the LH surge. These effects may explain the occasional induction of ovulation in anovulatory amenorrheic women when given progesterone to induce menses.

The LH surge acts quickly on both the granulosa and theca cells of the preovulatory follicle to terminate the genes involved in follicular expression and turn on the genes necessary for ovulation and luteinization. In addition, the LH surge initiates reentry of the oocyte into meiosis, expansion of the cumulus oophorus, synthesis of prostaglandins, and luteinization of granulosa cells. The mean duration of the LH surge is 48 hours, and ovulation occurs 36 to 40 hours after the LH surge onset (Hoff, 1983; Lemarchand-Beraud, 1982).

The surge is abruptly terminated and is thought to follow acutely augmented steroid and inhibin secretion by the corpus luteum. Alternatively, production of a gonadotropin surge-inhibiting/attenuating factor (GnSIF/AF) by either the ovary or hypothalamus also is postulated. The identity of this factor remains unknown (Vega, 2015).

The granulosa cells surrounding the oocyte, unlike mural granulosa cells, do not express LH receptors or synthesize progesterone. These cumulus oophorus granulosa cells develop tight gap junctions between themselves and with the oocyte. The cumulus mass that accompanies the ovulating oocyte is believed to provide a rough surface and larger size to improve oocyte "pick-up" by the tubal fimbria.

Amphiregulin, epiregulin, and betacellulin are recently discovered epidermal growth factor–like factors that can be substituted to elicit the morphologic and biochemical events triggered by LH (Hsieh, 2009). Thus, these growth factors are part of the downstream cascade that begins with LH binding to its receptor and ends with ovulation.

Based on sonographic surveillance, extrusion of the oocyte lasts only a few minutes (Fig. 16-18) (Knobil, 1994). The exact mechanism of this expulsion is poorly defined but is not due to a rise in follicular pressure (Espey, 1974). The presence of proteolytic enzymes in the follicle, including plasmin and collagenase, suggests that these enzymes are responsible for follicular wall thinning (Beers, 1975). The preovulatory gonadotropin surge stimulates expression of tissue plasminogen activator by the granulosa and theca cells. The surge also lowers expression of plasminogen inhibitor and leads to a marked increase in plasminogen activity (Piquette, 1993).

Prostaglandins also reach a peak concentration in follicular fluid during the preovulatory gonadotropin surge (Lumsden, 1986). Prostaglandins may stimulate smooth muscle contraction in the ovary and thereby aid ovulation (Yoshimura, 1987). Women undergoing infertility treatment are advised to avoid prostaglandin synthetase inhibitors in the preovulatory period to avoid *luteinized unruptured follicle syndrome (LUFS)* (Smith, 1996). Whether LUFS is considered pathologic or simply a sporadic event is controversial (Kerin, 1983).

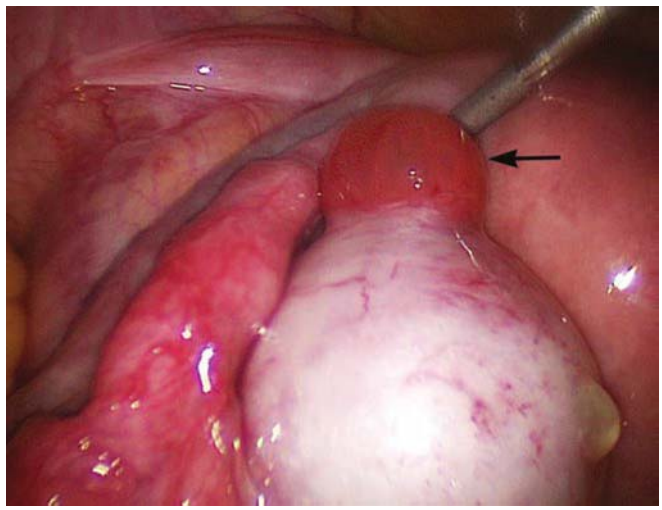

FIGURE 16-18 During laparoscopy, a stigma (*arrow*) on the ovarian surface prior to ovulation is seen. (Reproduced with permission from Dr. David Rogers.)

Luteal Phase

Following ovulation, the remaining follicular cells differentiate into the corpus luteum, literally *yellow body* (Corner, 1956). This process, which requires LH stimulation, includes both morphologic and functional changes known as *luteinization*. The granulosa and theca cells proliferate and undergo hypertrophy to form granulosa-lutein cells and smaller theca-lutein cells, respectively (Patton, 1991).

During corpus luteum formation, the basement membrane that separated granulosa cells from theca cells degenerates and allows vascularization of the previously avascular granulosa cells. Capillary invasion begins 2 days after ovulation and reaches the center of the corpus luteum by the fourth day. This augmented perfusion provides these luteal cells with access to circulating low-density lipoprotein (LDL), which is used to provide precursor cholesterol for steroid biosynthesis. This enhanced blood supply can also have clinical implications, and pain from a hemorrhagic corpus luteum cyst is a relatively frequent diagnosis in emergency rooms.

Steroidogenesis in the corpus luteum depends on adequate serum LH levels, LH receptors on luteal cells, and a sufficient number of luteal cells. Thus, it is critical that LH receptor expression on granulosa cells was appropriately induced during the prior follicular phase. Furthermore, blunted serum LH concentrations have been correlated with a shortened luteal phase. Luteal function is also influenced by gonadotropin levels from the preceding follicular phase. Reduced LH or FSH secretion is associated with poor luteal function. Presumably, a lack of FSH leads to fewer granulosa cells. Furthermore, luteal cells in these suboptimal cycles have fewer FSH-induced LH receptors and thus will be less responsive to LH stimulation.

The luteal phase is considered progesterone dominant, which contrasts with the estrogen dominance of the follicular phase. Increased vascularization, cellular hypertrophy, and more intracellular organelles transform the corpus luteum into

the most active steroidogenic tissue in the body. Maximal levels of progesterone production are observed in the midluteal phase and have been estimated at an impressive 40 mg of progesterone per day. Ovulation can be safely assumed to have occurred if the progesterone level exceeds 3 ng/mL on cycle day 21.

Although progesterone is the most abundant ovarian steroid during the luteal phase, estradiol also is produced in significant quantities. Estradiol levels drop transiently immediately after the LH surge and may explain the midcycle spotting noticed by some women. Although the reason is unknown, this estradiol decline may result from a direct inhibition of granulosa cell growth by rising progesterone levels (Hoff, 1983). Subsequent to this decline, estradiol levels steadily increase to reach a maximum during the midluteal phase.

The corpus luteum also produces large quantities of inhibin A. This coincides with a drop in circulating FSH levels in the luteal phase. If inhibin A levels decline at the end of the luteal phase, FSH levels rise once more to begin selection of an oocyte cohort for the next menstrual cycle.

If pregnancy does not occur, the corpus luteum regresses through a process called *luteolysis*. The mechanism is poorly understood, but luteal regression is presumed to be tightly regulated. Following luteolysis, the blood supply to the corpus luteum diminishes, progesterone and estrogen secretion drop precipitously, and the luteal cells undergo apoptosis and become fibrotic. This creates the *corpus albicans* (white body).

If pregnancy occurs, hCG produced by the early gestation "rescues" the corpus luteum from atresia by binding to and activating the LH receptor on luteal cells. hCG stimulation of corpus luteum steroidogenesis maintains endometrial stability until placental steroid production is adequate to assume this function late in the first trimester. For this reason, surgical removal of the corpus luteum during pregnancy should be followed by progesterone replacement as outlined in Chapter 6 (p. 139) until approximately 10 weeks' gestation.

ENDOMETRIUM

Menstrual Cycle Changes

The endometrium consists of two layers: the *basalis layer*, which lies against the myometrium, and the *functionalis layer*, which is apposed to the uterine lumen. The basalis layer does not change significantly across the menstrual cycle and serves as the reserve for endometrium regeneration following menstrual sloughing. The functionalis layer is further subdivided into the more superficial *stratum compactum*, a thin layer of gland necks and dense stroma, and the underlying *stratum spongiosum* containing glands and large amounts of loosely organized stroma and interstitial tissue.

After menstruation, the endometrium is 1 to 2 mm thick. Under the influence of estrogen, the glandular and stromal cells of the functionalis layer proliferate rapidly following menses (Fig. 16-19). This period of rapid growth, the *proliferative phase*, corresponds to the ovary's follicular phase. As this phase progresses, glands become more tortuous and cells lining the glandular lumen undergo pseudostratification. The stroma remains compact. Endometrial thickness approximates 12 mm at the time of the LH surge and does not increase significantly thereafter.

Following ovulation, the endometrium transforms into a secretory tissue. The time during and after this transformation is the *secretory phase* of the endometrium and correlates to the ovary's luteal phase. Glycogen-rich subnuclear vacuoles appear in cells lining the glands. Under further stimulation by progesterone, these vacuoles move from the glandular cells' base toward their lumen and expel their contents. This secretory process peaks on approximately postovulatory day 6 and coincides with the day of implantation. Throughout the luteal phase, glands become more tortuous, and the stroma becomes more edematous. In addition, spiral arteries that feed the endometrium increase their number and coiling.

If a blastocyst does not implant and the corpus luteum is not maintained by placental hCG, progesterone levels drop and endometrial glands begin to collapse. Polymorphonuclear leukocytes and monocytes from nearby vessels infiltrate the endometrium. The spiral arteries constrict, leading to local ischemia, and lysosomes release proteolytic enzymes that accelerate tissue destruction. Prostaglandins, particularly prostaglandin $F_{2\alpha}$, are present in the endometrium and likely contribute to arteriolar vasospasm. Prostaglandin $F_{2\alpha}$ also induces myometrial contractions, which may aid expelling the endometrial tissue.

The entire endometrial functionalis layer is thought to exfoliate with menstruation and leaves only the basalis layer to provide cells for endometrial regeneration. However, in studies, the amount of tissue shed from different levels of the endometrium varies widely. Following menstruation, reepithelialization of the desquamated endometrium is initiated within 2 to 3 days after menses onset and is completed within 48 hours.

Regulation of Endometrial Function

Tissue Degradation and Hemorrhage

Within the endometrium, numerous proteins maintain a delicate balance between tissue integrity and the localized destruction required for menstrual sloughing or for trophoblast invasion during implantation. Cytokines, growth factors, and steroid hormones are believed to regulate the genes encoding these tissue proteins (Maybin, 2012). Of these proteins, tissue factor, which is a membrane-associated protein, activates the coagulation cascade upon contact with blood. In addition, urokinase and tissue plasminogen activator (TPA) increase the conversion of plasminogen to plasmin to activate tissue breakdown. TPA activity is blocked by plasminogen activator inhibitor 1, which is present in endometrial stroma (Lockwood, 1993; Schatz, 1995). Another key mediator group is the matrix metalloproteinases (MMPs). This enzyme family has overlapping substrate specificities for collagens and other extracellular matrix components. The composition of MMPs varies within different endometrial tissues and during the menstrual cycle. Endogenous MMP inhibitor levels rise premenstrually and limit MMP degradative activity.

Vasoconstriction and Myometrial Contractility

Effective menstruation depends upon appropriately timed endometrial vasoconstriction and on myometrial contraction.

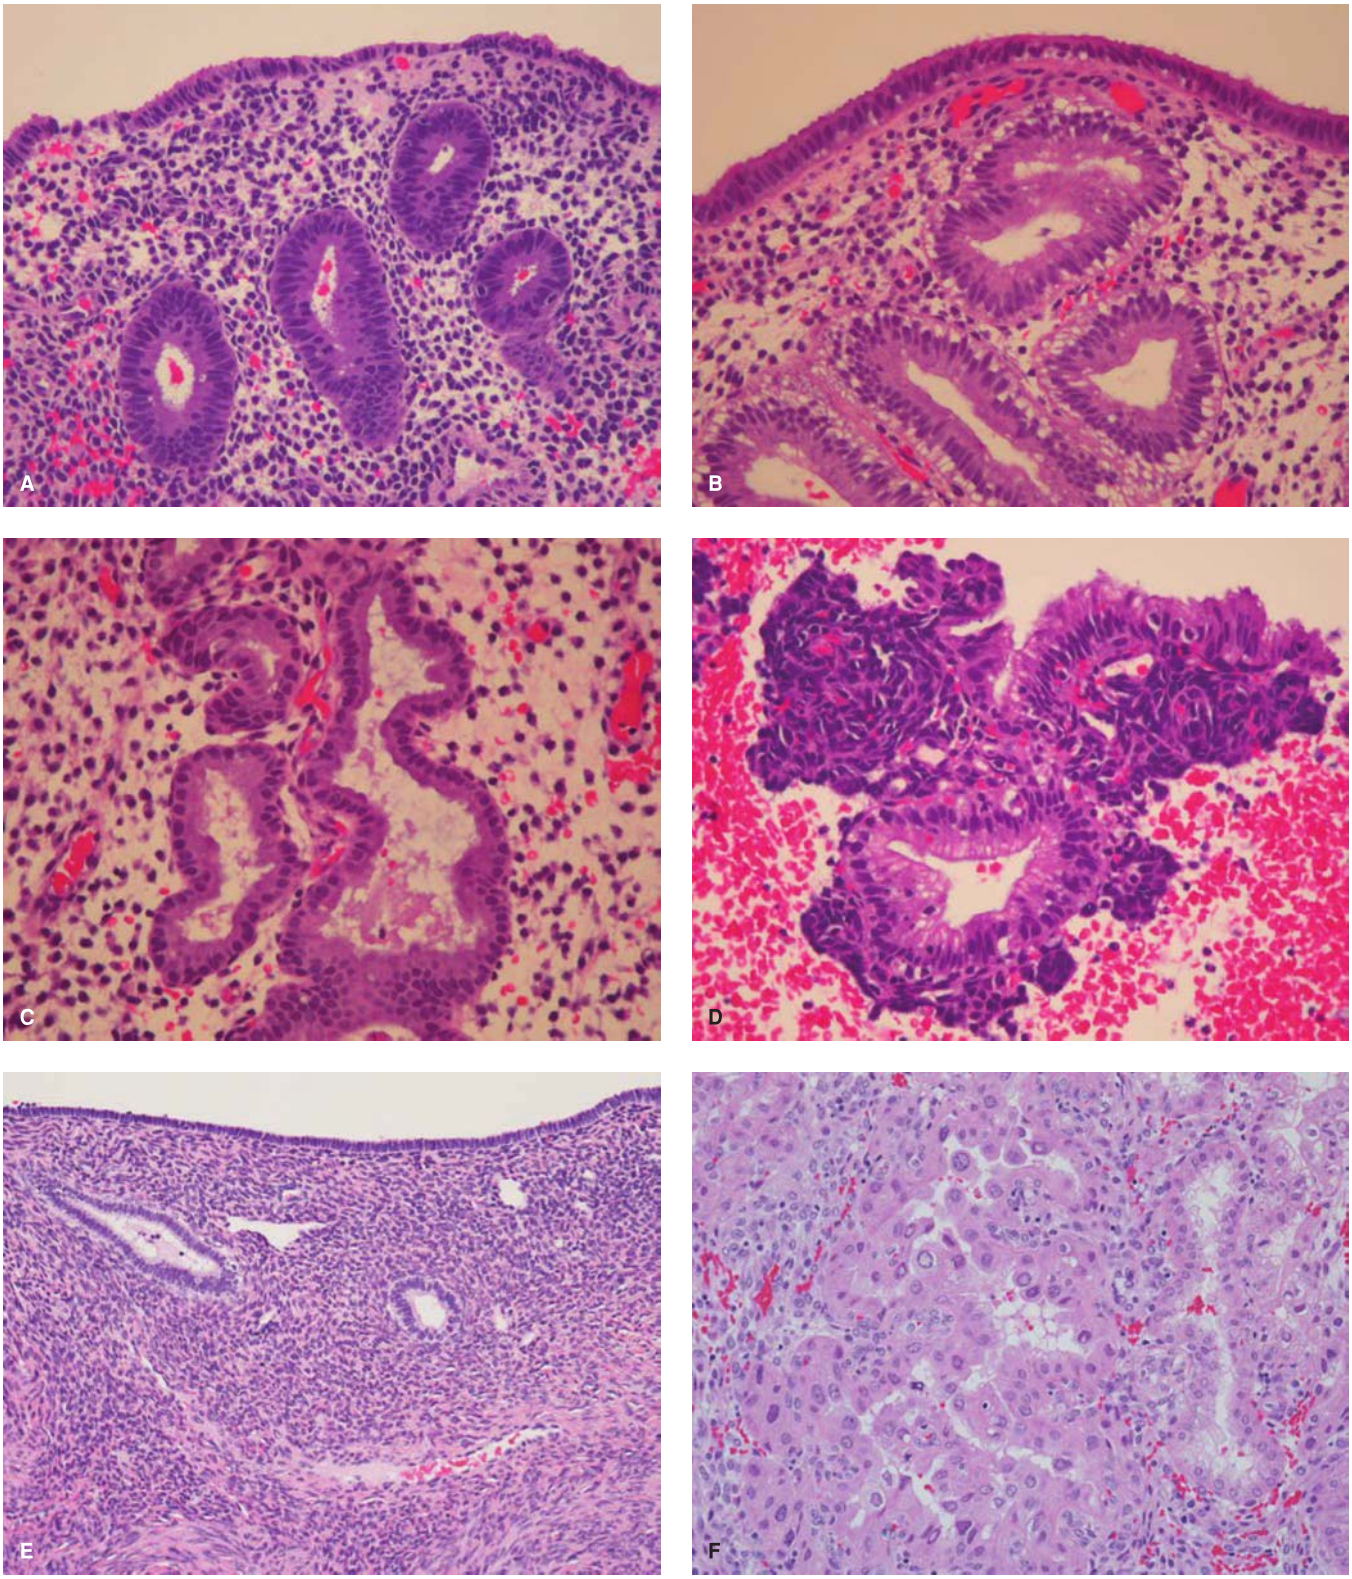

FIGURE 16-19 Endometrial changes during the menstrual cycle. **A.** Proliferative phase: straight to slightly coiled, tubular glands are lined by pseudostratified columnar epithelium with scattered mitoses. **B.** Early secretory phase: coiled glands with a slightly widened diameter are lined by simple columnar epithelium with clear subnuclear vacuoles. Stroma is variably edematous at this time. **C.** Late secretory phase: serrated, dilated glands with intraluminal secretion are lined by short columnar cells. **D.** Menstrual phase: fragmented endometrium with condensed stroma and glands with secretory vacuoles are seen in a background of blood. **E.** Atrophic endometrium: thin endometrium of the postmenopause has straight tubular glands lined by mitotically inactive, cuboidal epithelium. Stroma is dense and mitotically inactive. **F.** Gestational endometrium: hypersecretory glandular pattern featuring closely apposed glands with papillary infoldings and variable cytoplasmic vacuolization. The hypersecretory gland in the center shows the benign Arias-Stella reaction, with nuclear atypia characterized by variable nuclear enlargement, nuclear membrane irregularities, slight chromatin coarseness, nuclear vacuolization, and intranuclear pseudoinclusions. (Reproduced with permission from Dr. Kelley Carrick.)

Vasoconstriction produces ischemia, endometrial damage, and subsequent menstrual sloughing. Within the endometrium, epithelial and stromal cells secrete endothelin 1, a potent vasoconstrictor. Enkephalinase, an endothelin-degrading enzyme, is expressed at its highest levels in the midsecretory endometrium (Head, 1993). However, in the late luteal phase, the drop in serum progesterone leads to a loss of enkephalinase expression. This permits greater endothelin activity, which promotes an environment amenable to vasoconstriction.

In concert with endometrial sloughing, myometrial contractions control blood loss by compressing endometrial vessels and expelling menstrual discharge. A fall in serum progesterone levels lowers concentrations of an enzyme that degrades prostaglandins. This allows greater prostaglandin $F_{2\alpha}$ activity in the myometrium and triggers myometrial contractions (Casey, 1980).

Estrogens and Progestogens

The expression of estrogen and progesterone receptors in the endometrium is highly regulated across the menstrual cycle. This provides an additional mechanism for controlling steroid effects on endometrial development and function. Estrogen receptors are expressed in the nuclei of epithelial, stromal, and myometrial cells, and concentrations peak during the proliferative phase. However, during the luteal phase, rising progesterone levels blunt estrogen receptor expression. Endometrial progesterone receptors peak at midcycle in response to rising estrogen levels. By midluteal phase, progesterone receptor expression in the glandular epithelium is nearly absent, although expression remains strong in the stromal compartment (Lessey, 1988).

The proliferation and differentiation of the uterine epithelium is under the control of estradiol, progesterone, and various growth factors. The importance of estrogens for endometrial development is demonstrated by the predominance of endometrial hyperplasia in women receiving unopposed estrogen therapy. Estrogen interacts directly with estrogen receptors but also can indirectly induce various growth factors that include IGF-I, transforming growth factor α, and epidermal growth factor (Beato, 1989; Dickson, 1987). The effects of progesterone on endometrial growth vary among endometrial layers. Progesterone is critical for the conversion of the functionalis layer from a proliferative to a secretory pattern. Within the basalis layer, progesterone appears to promote cellular proliferation.

Growth Factors and Cell Adhesion Molecules

Numerous growth factors and associated receptors act in the endometrium. Each factor has its own pattern of expression, making it difficult to determine which factor is most critical for endometrial function (Ohlsson, 1989; Sharkey, 1995).

In addition to growth factors, cell adhesion molecules play an important role in endometrial function. These molecules fall into four classes: integrins, cadherins, selectins, and members of the immunoglobulin superfamily. Each has been implicated in endometrial regeneration and embryo implantation, discussed next.

Implantation Window

The embryo enters the uterine cavity 2 to 3 days after fertilization, and implantation begins approximately 4 days later. Normal implantation and embryonic development require synchronous development of the endometrium and the embryo (Pope, 1988). However, the human blastocyst may have less stringent implantation requirements than other species, as ectopic implantation occurs relatively frequently.

Uterine receptivity is defined as the temporal window of endometrial maturation during which trophectoderm attaches to endometrial epithelial cells and subsequently invades into endometrial stroma. The implantation window in humans is relatively broad and extends from day 20 through 24 of the menstrual cycle. Precise determination of this temporal window is critical since only those factors expressed during this time act as direct functional mediators of uterine receptivity.

Endometrial receptivity is associated with loss of surface microvilli and ciliated cells and with development of cellular protrusions, called *pinopods*, on the apical surface of the endometrium. Pinopods are considered an important morphologic marker of peri-implantation endometrium. Pinopod formation is highly progesterone dependent (Yoshinaga, 1989).

Cell adhesion molecules, immunoglobulins, and cytokines are believed to be necessary for uterine receptivity. Integrins are particularly well studied in this regard (Casals, 2010). Clinically, finding a panel of markers that would noninvasively diagnose an endometrial implantation abnormality or determine the implantation window would greatly aid infertility evaluation and treatment. However, at this time, despite substantial effort, no currently available test has demonstrated the reliability or reproducibility to warrant acceptance.

The term *luteal phase defect* describes dyssynchrony between endometrial development and menstrual cycle phase that leads to subsequent implantation failure and early pregnancy loss (Noyes, 1950; Olive, 1991). This term currently has limited utility in clinical practice, because of our inability to accurately diagnose or treat the disorder.

Following implantation, the endometrium undergoes essential remodeling by invading trophoblast. In addition, the maternal endocrine environment changes extensively because of altered maternal physiology and contributions by the placenta and fetus. A more detailed discussion of these changes is found in *Williams Obstetrics*, 25th edition (Mahendroo, 2018a).

HYPOTHALAMIC-PITUITARY AXIS ABNORMALITIES

Classically, abnormalities in this axis result in low gonadotropin and resultant low sex steroid levels. Termed *hypogonadotropic hypogonadism*, this can be developmental or acquired. Developmental lesions due to inherited genetic defects include Kallmann syndrome and idiopathic hypogonadotropic hypogonadism. Acquired abnormalities include functional disorders (eating disorders, excessive exercise, stress) and hypothalamic-pituitary lesions due to tumor, infiltrative diseases, infarction, surgery, or radiation therapy. Information regarding hypothalamic disorders and other causes of hypogonadotropic hypogonadism can be found in Chapter 17 (p. 377). Hyperprolactinemia and pituitary adenomas are discussed here.

Hyperprolactinemia

Etiology

Elevated circulating PRL levels can be caused by various physiologic activities including pregnancy, sleep, eating, and coitus. Increased PRL levels, which in general can lead to galactorrhea, may also be observed following chest wall stimulation such as occurs with suckling, breast examination, chest wall surgery, herpes zoster infection, or nipple piercing (Table 13-2, p. 285). PRL is primarily regulated by tonic inhibition of dopamine secretion. PRL secretion is increased by serotonin, norepinephrine, opioids, estrogen, and TRH. Therefore, medications that block dopamine-receptor action (phenothiazines) or increase catecholamine levels (monoamine oxidase inhibitors) may increase PRL levels. Moreover, hyperprolactinemia may be caused by cranial tumor, radiation, or infiltrative diseases such as sarcoid and tuberculosis. These can damage the pituitary stalk and thereby prevent dopamine-mediated inhibition of PRL secretion.

Primary hypothyroidism also is associated with mild elevations in serum PRL levels. Specifically, low circulating thyroid hormone levels produce a reflex rise in hypothalamic TRH levels due to loss of feedback inhibition. TRH can bind directly to anterior pituitary gland lactotropes and stimulate PRL production. As a rule, thyroid function tests should be performed when confirming a diagnosis of hyperprolactinemia, as a patient may require thyroid replacement rather than further evaluation for pituitary adenoma (Hekimsoy, 2010).

Prolactin-secreting adenomas, also termed *prolactinomas*, are the most common pituitary adenoma and the most common adenomas to be diagnosed by gynecologists. Affected women typically present with microadenomas and signs of PRL excess such as galactorrhea and amenorrhea.

Diagnosis

Hyperprolactinemia is, by definition, present in any patient with an elevated serum PRL level. Optimally, PRL levels are drawn in the morning, that is, at the PRL nadir. Prior to testing, breast examination is avoided to prevent false-positive results. If a mildly elevated PRL level is found, sampling is repeated because PRL levels vary throughout the day. Moreover, many factors including the stress of venipuncture may produce false elevations.

Normal PRL levels are typically <20 ng/mL in nonpregnant women, although the upper limit of normal varies by assay. Importantly, PRL levels rise nearly 10-fold during pregnancy and make detection of a prolactinoma difficult at this time. Occasionally, the reported PRL value will be falsely low due to a "hook effect" present in the assay and discussed earlier (p. 343) (Frieze, 2002). Importantly, a mismatch between the adenoma size noted on magnetic resonance (MR) imaging and the degree of PRL level elevation should alert a clinician to either the possibility of an incorrect assay result or the likelihood that the macroadenoma is actually not primarily PRL secreting. Macroadenomas of any cell type may damage the pituitary stalk and prevent transfer of hypothalamic dopamine to the lactotropes.

Conversely, a patient may rarely have an elevated PRL level on assay despite a lack of clinical features of hyperprolactinemia. The hyperprolactinemia in these patients is thought to be secondary to alternate forms of PRL, including the so-called *big prolactin* or *macroprolactin*, which contains multimers of native PRL. Macroprolactin is not physiologically active but may be detected by PRL assays (Fahie-Wilson, 2005).

For all patients with confirmed hyperprolactinemia, MR imaging is advisable. Some advocate limiting imaging to women with a PRL level >100 ng/mL, as lower levels are most likely due to small microadenomas (Fig. 16-20). Although this is undoubtedly a safe approach in most women, mildly elevated PRL levels may also be due to pituitary stalk compression by a non-prolactin-secreting macroadenoma or a craniopharyngioma, which are diagnoses with severe potential consequences.

The availability of sensitive neuroimaging techniques now affords earlier diagnosis and intervention. Although computed tomography (CT) scanning provides useful information on tumor size, bony artifacts may limit interpretation. Therefore, MR imaging, using both T1- and T2-weighted images, has become the preferred radiologic approach due to its high sensitivity and excellent spatial resolution (Ruscalleda, 2005).

Frequently, MR imaging is performed with and without gadolinium contrast to highlight anatomy.

Associated Amenorrhea

The primary mechanism linking hyperprolactinemia and amenorrhea is believed to be a reflex rise in central dopamine levels. Stimulation of the dopaminergic receptors on the GnRH neurons alters GnRH pulsatility, thereby disrupting folliculogenesis. As dopamine receptors have also been identified in the ovaries, detrimental effects on folliculogenesis also may play a role. Additional mechanisms undoubtedly exist in view of the complex interactions that influence hypothalamic function.

Pituitary Adenomas

Classification

Pituitary adenomas are the most common cause of acquired pituitary dysfunction and constitute approximately 15 percent of all intracranial tumors (Melmed, 2015; Pekic, 2015). Clinically, symptoms of galactorrhea, menstrual disturbances, or infertility may lead to its diagnosis. Most tumors are benign, and only an estimated 0.1 percent of adenomas develop into frank carcinoma with metastasis (Kaltsas, 2005). Nevertheless, pituitary adenomas may cause striking abnormalities in both endocrine and nervous system function.

Pituitary adenomas were historically classified as eosinophilic, basophilic, or chromophobic according to their hematoxylin and eosin staining characteristics. Tumors are now classified by their hormonal expression pattern as determined by immunohistochemistry (Fig. 16-21). Adenomas are further grouped by size into *microadenomas* (<10 mm in diameter) and *macroadenomas* (>10 mm in diameter).

Most adenomas secrete PRL, however, adenomas may release any of the pituitary hormones (Table 16-6). These may be secreted either as a single hormone (monohormonal adenoma) or in combinations (multihormonal adenoma). In the past, a subset of tumors was considered nonsecreting. However, with more sensitive assays, most have been determined to secrete the common α-subunit or the gonadotropin β-subunits and therefore are gonadotrope-derived. Rarely, both α- and β-subunits are secreted as functional dimeric hormone.

Symptoms

Pituitary adenomas may cause symptoms via excess hormone secretion and lead to hyperprolactinemia, acromegaly, or Cushing disease. Alternatively, adenomas may result in hormone deficiency due to damage of other pituitary cell types or the pituitary stalk by an expanding adenoma or following treatment of the primary lesion.

As might be predicted, pituitary microadenomas are typically diagnosed during evaluation of an endocrinopathy. Macroadenomas frequently present with patient symptoms from invasion of surrounding structures. The anterior pituitary gland neighbors both the optic chiasm and cavernous sinuses. Disruption of the optic chiasm by suprasellar growth of the pituitary mass may create bitemporal hemianopsia, in which the outer portion of the right and left visual fields is lost. The cavernous sinuses are a paired collection of thin-walled veins located on either side of the sella turcica. Pituitary tumor compression can lead to cavernous sinus syndrome. This constellation of symptoms includes headache, visual disturbances, and cranial nerve palsies, specifically of cranial nerves III, IV, and VI.

Any pituitary mass can lead to reproductive dysfunction that may include delayed puberty, anovulation, oligomenorrhea, and infertility. The exact mechanisms linking adenomas to menstrual dysfunction are not well understood for many adenoma subtypes, with the exception of prolactinomas. Macroadenomas likely affect reproductive function either by compressing the

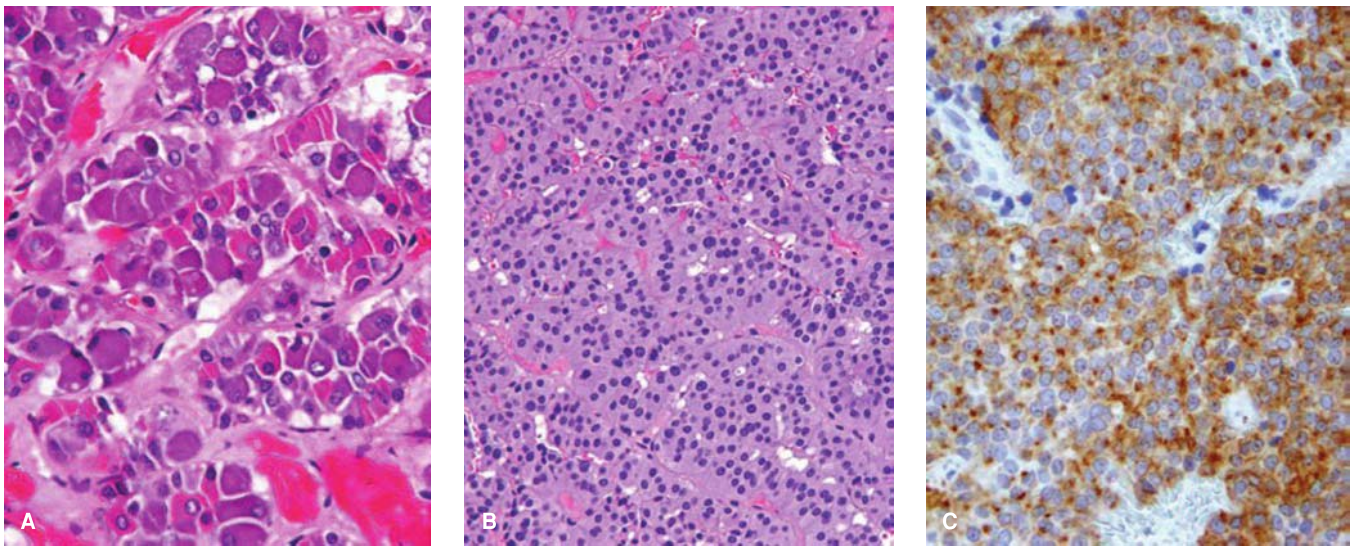

FIGURE 16-21 Photomicrographs from the anterior pituitary gland. **A.** Normal anterior pituitary gland. Secretory cells of the various types are arranged in small clusters between sinusoidal capillaries. **B.** Pituitary adenoma. In contrast to normal anterior pituitary gland, adenomas are composed of highly monomorphic cells. Note the absence of small clusters and sinusoids. **C.** Prolactin-secreting adenoma. Immunohistochemistry demonstrates expression of prolactin by many of the neoplastic cells. The dotlike pattern is characteristic of many prolactin-producing adenomas. TABLE 16-6. Clinical Features of Pituitary Adenomas

Adenoma Cell Origin (Hormone)	Clinical Syndrome	Testing[a]	Typical Results	Treatment
Lactotrope (PRL)	Galactorrhea; hypogonadism	PRL	Elevated	Dopamine agonist; surgical excision
Gonadotrope (LH, FSH, free subunits)	Silent or hypogonadism; rarely gonadotrope excess	Free α-, FSHβ-, and LHβ-subunits	Elevated	Surgical excision
Somatotrope (GH)	Acromegaly or gigantism; menstrual irregularity	IGF-I; 100-g glucose suppression test	Elevated; no GH suppression	Surgical excision; somatostatin analogues
Corticotrope (ACTH)	Cushing syndrome; amenorrhea	ACTH; 24-hour urinary free cortisol; dexamethasone suppression	Elevated ACTH and cortisol; no suppression	Surgical excision; ketoconazole to blunt adrenal steroidogenesis
Thyrotrope (TSH)	Thyrotoxicosis; menstrual abnormalities	TSH, T_3, and T_4	All elevated	Surgical excision; PTU or methimazole; β-blockers for tachycardia

[a]All tests are serum measurements except for urinary free cortisol.
ACTH = adrenocorticotropin hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GnRH = gonadotropin-releasing hormone; IGF = insulin-like growth factor; LH = luteinizing hormone; PRL = prolactin; PTU = propylthiouracil; SHBG = sex hormone–binding globulin; TSH = thyroid-stimulating hormone; T_3 = triiodothyronine; T_4 = thyroxine.

pituitary stalk, which results in hyperprolactinemia, or, less commonly, by directly compressing gonadotropes.
